Preface

The encyclopedia and handbook represents an update of existing materials, parts, finishes (coatings), systems, and processes and includes new materials that have been invented or changed or modified either by new processes or by additions or innovative techniques—the book covers basic materials from “A” to “Z.”

This encyclopedia is the culmination of over 70 years of various encyclopedias and material handbooks. With the advent of a steady increase in the number of materials and processes being developed over these past years, it is hoped that a one-volume encyclopedia would intelligently describe the important characteristics of commercially available materials without going into the details—an encyclopedia/handbook that would meet the job needs of managers and executives, purchasing and manufacturing managers, supervisors, engineers, metallurgists, chemists, students, technologists, teachers, and others.

The encyclopedia reflects the phenomenal proliferation in the number and variety of materials, processes, parts, coatings, and systems. More than 16,000 different materials are described. Despite this manifold increase over the years, it is virtually impossible to include all commercially available materials in a one-volume work of this kind. Nevertheless, the most important and most widely used of the thousands of materials introduced every year are included in this updated edition.

The diverse technologies that make up the field of materials and structures are at varying stages of commercialization. For example, piezoelectric and electrostrictive ceramics, piezoelectric polymers, and fiber-optic sensor systems are well-established commercial technologies, whereas microelectromechanical systems (MEMS), magnetostrictive materials, shape memory alloys (SMA) and polymers, conductive polymers, engineering-grade thermoplastics, nanomaterials, additive manufacturing (AM), and static-dissipative ABS plastics are, in some cases, in their developmental stages of commercialization.

There has been a tremendous increase in the variety of materials and processes, especially in the medical field, coupled with the rise of new and more severe service requirements, rigid testing, and qualification requirements, as well as a demand for lower cost. This has brought about many changes in the way these materials are utilized. Traditionally, users fit the design of a product to the properties of the material it was made of. This attitude has changed. The major concern now is finding and applying a material or materials with the right combination of properties to meet design and service conditions. Today, material selection is a complex process that operates throughout the entire span of a product's evolution. Thus, the new attitude is end-service oriented. The next logical step, of course, is tailor-made materials.

Analytical procedures have been developed to deal with the complex interaction between requirements and

performance properties. And materials engineering departments and specialists who devote their full time to material selection problems are now a common adjunct to engineering or manufacturing departments.

As we will see, scientists, researchers, and technologists no longer accept the atomic arrangements nature gives us. Such is the case with, for example, high polymers, aggregates of giant, chain-like molecules. High polymers that nature gives us, such as wood, leather, and glue, have been used in engineering materials for centuries. But only during the past couple of decades have we acquired sufficient understanding of their molecular structure to improve upon nature. Now, by varying the chain length and degree of branching or cross-linking, materials can be produced with combinations of properties to meet specific application requirements.

The past century was dominated by the influence of emerging materials that were shaped and transformed into new mass-produced products that defined the twentieth century. Plastics, composites, aluminum, and advanced ceramics facilitated innovations that influenced culture and let us form products and machinery that made our lives easier—brightly colored plastics that pushed through labor-saving devices, materials engineered to make cars more comfortable, and touchscreen interactivity that simplified complex technology.

The next phase of material innovation is going to be a little more subtle and inconspicuous—not driven by materials and products that we can see, but rather by materials whose performance is more under the radar. These innovations are likely to manifest themselves through materials that intuitively make decisions for us. There is an increasing number of materials being developed as a response to how we live now and how we will live in the future. These new materials are often incorporating nanotechnology in some way to enhance performance or adapt, over time, to sensors and with the intention of improving our day-to-day life. Some materials that encompass this area are as follows:

- Nanocoated fabric, which repels stains
- Phase-change fabric
- Noise-absorbing material
- Self-healing plastic film
- Biodegradable additive for plastics
- Mineral plaster, which removes odor
- Foam crash mats, which keep you safe on the slopes

With regard to alloy names—metals, plastics, ceramics, and other material types—the choice between inclusion and exclusion is inevitably arbitrary. At one extreme, it would be ridiculous to offer an encyclopedia that excluded terms such as brass and solder or even admiralty brass or sterling silver. At the other extreme, it would be impossible, even assuming if it was desirable, to include all of the immense number of names introduced, and often discarded, at the whim

of a manufacturer. The aim, therefore, will be to include all generic names, such as those mentioned here, together with a small number of trade or proprietary names, such as Dural and Nimonic, that are commonly used.

The aim of this book is to reflect the broadest usage of materials and processing technology that is current, and, furthermore, limited reference will be made to some terms once popular, but now fallen from favor. Consequently, a very large number of books, reports, and papers, and even conversations,

have been absorbed in an attempt to provide a consensus and comprehensive view. Thus, rather than attempting the invidious task of identifying individual sources or influences, I prefer to offer thankful knowledge with gratitude to the many material engineers, metallurgists, technologists, scientists, chemists, and others whose work has directly or indirectly been utilized or described in this encyclopedia.

Mel Schwartz

A

A

The symbol for a repeating unit in a polymer chain.

Å

Angstrom, a unit of measure, 10^{-10} m.

A, A₁, A_c, etc.

Designations of critical temperatures in the transformation of steel.

ABA Copolymers

Block copolymers with three sequences but only two domains.

A-Basis

The "A" mechanical property value is the value above which at least 99% of the population of values is expected to fall, with a confidence of 95%. Also called A-allowable. See also *B-basis*, *S-basis*, and *typical-basis*.

Aberration

In microscopy, any error that results in image degradation. Such errors may be chromatic, spherical, astigmatic, chromatic, distortion, or curvature of field and can result from design or execution, or both.

Adhesive

A material that resists adhesion. A film or coating applied to surfaces to prevent sticking, heat sealing, and so on, such as a parting agent or mold release agent.

Ablative Plastic

A material that absorbs heat (with a low material loss and char rate) through a decomposition process (pyrolysis) that takes place at or near the surface exposed to the heat. This mechanism essentially provides thermal protection (insulation) of the subsurface materials and components by sacrificing the surface layer. Ablation is an exothermic process.

Ablatives

Materials used for the outward dissipation of extremely high heats by mass removal. Their most common use is as an external heat shield to protect supersonic aerospace vehicles from an excessive buildup of heat caused by air friction at the surface. The ablative

material must have a low thermal conductivity in order that the heat may remain concentrated in the thin surface layer. As the surface of the ablator melts or sublimates, it is wiped away by the frictional forces that simultaneously heat newly exposed surfaces. The heat is carried off with the material removed. The less material that is lost, the more efficient is the ablative material. The ablative material also should have a high thermal capacity in the solid, liquid, and gaseous states, a high heat of fusion and evaporation, and a high heat of dissociation of its vapors. The ablative agent, or ablator, is usually a carbonaceous organic compound, such as a phenolic plastic. As the dissociation products are lost as liquid or vapor, the char is held in place by the refractivity reinforcing fibers, still giving a measure of heat resistance. The effective life of an ablative is short, calculated in seconds per millimeter of thickness for the distance traveled in the atmosphere.

Single ablative materials seldom have all of the desirable factors, and thus composites are used. Phenolic or epoxy resins are reinforced with asbestos fabric, carbonized cloth, or refractory fibers, such as asbestos, fused silica, and glass. The refractory fibers not only are incorporated for mechanical strength but also have a function in the ablative process, and surface-active agents may be added to speed the rate of evaporation. Ablative paint, for protecting woodwork, may be organic silicones, which convert to silica at temperatures above 2000°F (1093°C).

Abnormal Steel

A steel with variable hardenability leading to local soft spots when components are hardened. In the annealed or normalized conditions, these areas comprise abnormally coarse and irregular pearlite. The effect is associated with segregation of alloy elements or variation and aluminum (deoxidizer) content.

Abrasion

(1) A process in which hard particles or protuberances are forced against and moved along a solid surface. (2) A roughening or scratching of a surface due to abrasive wear. (3) The process of grinding or wearing away through the use of abrasives. The mechanism is predominantly a mechanical cutting action as opposed to the repeated welding/tearing action involved in adhesive wear.

Abrasion Artifact

A false structure introduced during an abrasion stage of a surface-preparation sequence.

Abrasion Fluid

A liquid added to an abrasion system. The liquid may act as a lubricant, as a coolant, or as a means of flushing abrasion debris from the abrasion track.

A

Abrasion Process

An abrasive machining procedure in which the surface of the workpiece is rubbed against a 2D array of abrasive particles under approximately constant load.

Abrasion Rate

The rate at which material is removed from a surface during abrasion. It is usually expressed in terms of the thickness removed per unit of time or distance traversed.

Abrasion Resistance

The ability of the material to resist surface wear.

Abrasion Soldering

A soldering process variation in which the faying surface of the base metal is mechanically abraded during soldering.

Abrasive

(1) A hard substance used for grinding, honing, lapping, superfinishing, polishing, pressure blasting, or barrel finishing. Abrasives in common use are natural and artificial. The natural abrasives include the diamond, emery, corundum, sand, crushed garnet and quartz, tripoli, and pumice. Artificial abrasives, or manufactured abrasives, are generally superior in uniformity to natural abrasives and are mostly silicon carbide, aluminum oxide, boron carbide, or boron nitride, marketed under trade names. Artificial diamonds are also now being produced. The massive natural abrasives, such as sandstone, are cut into grinding wheels from the natural block, but most abrasive materials are used as grains or built into artificial shapes.

For industrial grinding, artificial abrasives are preferred to natural abrasives because of their greater uniformity. Grading is important because uniform grinding requires grains of the same size. The abrasive grains are used as a grinding powder, are made into wheels, blocks, or stones, or are bonded to paper or cloth. An abrasive belt is a coated abrasive product in the form of a belt, used in production grinding and polishing.

Abrasive Blasting

A process for cleaning or finishing by means of an abrasive directed at high velocity against the workpiece.

Abrasive Cloth

It is made of cotton jean or drills to close tolerances of yarns and weaves, and the grains are attached with glue or resin.

Abrasive Disk

(1) A grinding wheel that is mounted on a steel plate, with the exposed flat side being used for grinding. (2) A disk-shaped, coated abrasive product.

Abrasive Erosion

Erosive wear caused by the relative motion of solid particles, which are entrained in a fluid, moving nearly parallel to a solid surface.

Abrasive Flow Machining

Removal of material by a viscous, abrasive media flowing under pressure through or across a workpiece.

Abrasive Jet Machining

Material removal from a workpiece, by impingement of fine abrasive particles, which are entrained in a focused, high-velocity gas stream.

Abrasive Machining

A machining process in which the points of abrasive particles are used as machining tools. Grinding is a typical abrasive machining process.

Abrasive Paper

Has the grains, usually aluminum oxide or silicon carbide, glued to one side of 40–130 lb kraft paper. The usual grain sizes are No. 16 to No. 500.

Abrasive Powder

Usually graded in sizes from 8 to 240 mesh. Coarse grain is to 24 mesh; fine-grain is 150–240. Levigated abrasives are fine powders for final burnishing of metals or for metallographic polishing, usually processed to make them chemically neutral. Green rouge is levigated chromic oxide, and mild polish may be levigated tin oxide; both are used for burnishing soft metals. Polishing powder may be aluminum oxide or metal oxide powders of ultrafine particle size down to 600 mesh.

Abrasive Sand

Any sand used for abrasive and grinding purposes, but the term does not include the sharp grains obtained by crushing quartz and used for sandpaper. The chief types of abrasive sand include sandblast sand, glass-grinding sand, and stone-cutting sand. Sand for stone sawing and for marble and glass grinding is usually ungraded, with no preparation other than screening, but it must have tough, uniform grains.

Abrasive Tumbling

See *barrel finishing*.

Abrasive Wear

The removal of material from a surface when hard particles slide or roll across the surface under pressure. The particles may be loose or may be part of another surface in contact with the surface being abraded. Compare with adhesive wear.

Abrasive Wheel

A grinding wheel composed of an abrasive grit and a bonding agent. Grinding of abrasive wheels is by grit size number from No. 10 to No. 600, which is 600 mesh; by grade of wheel, or strength of the bond, which is by letter designation, increasing in hardness from A to Z; and by grain spacing or structure number. The ideal condition is with a bond strong enough to hold the grains

to accomplish the desired result and then release them before they become too dull. Essential qualities in the abrasive grain are penetration hardness, body strength sufficient to resist fracture until the points dull and then break to present a new edge, and an attrition resistance suitable to the work. Some wheels are made with a porous honeycombed structure to give free cutting and cooler operation on some types of metal grinding. Some diamond wheels are made with aluminum powder mixed with a thermosetting resin, and the diamond abrasive mix is hot pressed around this core wheel. Norton diamond wheels are of three types: metal bonded by powder metallurgy, resinoid bonded, and vitrified bonded.

Aluminum oxide wheels are used for grinding materials of high tensile strength. Silicon carbide is harder but is not as strong as aluminum oxide. It is used for grinding metals that have dense grain structure and for stone. Vitrified wheels are made by molding under heat and pressure. They are used for general and precision grinding where the wheel does not exceed a speed of 6500 surface ft/min (33 m/s). The rigidity gives high precision, and the porosity and strength of bond permit high stock removal. Silicate wheels have a silicate binder and are baked. The silicate bond releases the grains more easily than the vitrified and is used for grinding edge tools to reduce burning of the tool. Synthetic resins are used for bonding where greater strength is required and is obtained with the silicate, but less openness than with the vitrified. Resinoid bonds are used up to 16,000 surface ft/min (81 m/s) and are used especially for thread grinding and cut off wheels. Shellac binder is used for light work and for high finishing. Rubber is used for precision grinding and for centerless-feed machines.

Mild abrasives, uses silver polishes and window-cleaning compounds, such as chalk and talc, have a hardness of 1–2 Mohs. The milder abrasives for dental pastes and powders may be precipitated calcium carbonate, tricalcium phosphate, or combinations of sodium metaphosphate and tricalcium phosphate. Abrasives for metal polishes may also be pumice, diatomite, silica flour, tripoli, whiting, kaolin, tin oxide, or fuller's earth. This type of fine abrasive must be of very uniform grain in order to prevent scratching.

Abrasivity

The extent to which a surface, particle, or collection of particles will tend to cause abrasive wear when forced against a solid surface under relative motion and under prescribed conditions.

ABS Plastics

The letters ABS identify the family of acrylonitrile–butadiene–styrene resins. Common trade names for these materials are Cycolac, Magnum, and Lustran. ABS resins belong to a very versatile family of engineering thermoplastics, produced by combining three monomers—acrylonitrile, butadiene, and styrene—by a variety of methods involving polymerization, graft polymerization, physical mixing, and combinations thereof. Each monomer is an important component of ABS. Acrylonitrile contributes heat resistance, chemical resistance, and surface hardness to the system. The styrene component contributes processibility, rigidity, and strength. Butadiene contributes toughness and impact resistance. This family of plastics generally are opaque and distinguished by a good balance of properties, including high impact strength, rigidity, and hardness over a temperature range of -40°F to 230°F (-40°C to 110°C). Compared to other structural engineering plastics, they are generally considered to fall at the lower end of the scale. Medium impact grades are hard, rigid, and tough and are used for appearance parts

that require high strength, good fatigue resistance, and surface hardness and gloss. High impact grades are formulated for similar products where additional impact strength is gained at some sacrifice in rigidity and hardness. See Table A.1.

ABS plastics are two-phase systems. Styrene–acrylonitrile (SAN) forms the continuous matrix phase. The second phase is composed of dispersed polybutadiene particles, which have a layer of SAN grafted onto their surface. The layer of SAN at the interface makes the two phases compatible.

ABS plastics are readily processed by extrusion, injection molding, blow molding, calendering, and vacuum forming. Resins have been developed especially for cold forming or stamping from extruded sheet. Typical applications are helmets, refrigerator liners, luggage tote trays, housings, grills for hot air systems, and pump impellers. Extruded shapes include tubing and pipe. ABS-plated parts are now in wide use, replacing metal parts in the automotive and appliance field.

Absolute Density

See *density* and *absolute*.

Absolute Humidity

The weight of water vapor present in a unit volume of air, such as grams per cubic foot or grams per cubic meter. The amount of water vapor is also reported in terms of weight per unit weight of dry air, such as grams per pound of dry air, but this value differs from values calculated on a volume basis and should not be referred to as absolute humidity. It is designated as humidity ratio, specific humidity, or moisture content.

Absolute Impact Velocity

See *impact velocity*.

Absolute Pore Size

The maximum pore opening of a porous material, such as a filter, through which no large particle will pass.

Absolute Temperature

The temperature related to absolute zero. On the Celsius (centigrade, C) scale, 0° Kelvin (K) is -273.15°C and 1 Kelvin degree interval equals 1 Celsius degree interval. On the Fahrenheit (F) scale, 0° Rankine (R) is -459.67° Fahrenheit and 1 Rankine degree interval equals 1 Fahrenheit degree interval.

Absolute Viscosity

See *viscosity*.

Absorbance (A)

The logarithm to the base 10 of the reciprocal of the transmittance. The preferred term for photography is optical density.

Absorber

(1) A material capable of physically assimilating others. In a nuclear context, an absorber is a material capable of accepting and retaining

TABLE A.1

Properties of Acrylonitrile–Butadiene–Styrene and Styrene–Acrylonitrile

		Standard Acrylonitrile–Butadiene– Styrene Grades			Special-Purpose Acrylonitrile–Butadiene–Styrene Grades					Styrene–Acrylonitrile Grades

a large number of neutrons without fission. (2) A material or component intended to absorb kinetic energy as in the shock absorber of a vehicle.

Absorption

(1) The taking up of a liquid or gas by capillary, osmotic, or solvent action. (2) The capacity of a solid to receive and retain a substance, usually a liquid or gas, with the formation of an apparently homogeneous mixture. (3) Transformation of radiant energy to a different form of energy by interaction with matter. (4) The process by which a liquid is drawn into and tends to fill permeable pores in a porous solid body; also, the increase in mass of a porous solid body resulting from the penetration of a liquid into its permeable pores. See also *adsorption*.

Unless otherwise stated, it is usually implicit that the interaction is physical, there is no chemical reaction or alloying.

Absorption Contrast

In transmission electron microscopy, image contrast caused by differences in absorption within a sample due to regions of different mass density and thickness.

Absorption Edge

The wavelength or energy corresponding to a discontinuity in the plot of absorption coefficient versus wavelength for a specific medium.

Absorption Spectroscopy

The branch of spectroscopy treating the theory, interpretation, and application of spectra originating in the absorption of electromagnetic radiation by atoms, ions, radicals, and molecules.

Absorptive Lens (Eye Protection)

A filter lens whose physical properties are designed to attenuate the effects of glare and reflected and stray light. See also *filter plate*.

Absorptivity

A measure of radiant energy from an incident beam as it traverses an absorbing medium, equal to the absorbance of the medium divided by the product of the concentration of the substance and the sample half-life. Also known as *absorption coefficient*.

AC

Alternating current.

AC

See *acetal copolymers*, *acetal homopolymers*, and *acetal resins*.

AC Noncapacitive Arc

A high-voltage electrical discharge used in spectrochemical analysis to vaporize the sample material. See also *DC intermittent noncapacitive arc*.

A.C.P.D.

Alternating current, potential drop; a technique for measuring crack propagation, see *potential drop*.

Accelerated Aging

A process by which the effects of aging are accelerated under extreme and/or cycling temperature and humidity conditions. The process is meant to duplicate long-time environmental conditions in a relatively short space of time.

Accelerated Corrosion Test

Method designed to approximate, in a short time, the deteriorating effect under normal long-term service conditions.

Accelerated Life Test

A method designed to approximate, in a short time, the deteriorating effect obtained under normal long-term service conditions. See also *artificial aging*.

Accelerated Testing

A test performed on materials or assemblies that are meant to produce failures caused by the same failure mechanism as expected in field operation but in significantly shorter time. The failure mechanism is accelerated by changing one or more of the controlling test parameters.

Accelerating Potential

(1) A relatively high voltage applied between the cathode and anode of an electron gun to accelerate electrons. (2) The potential in electron beam welding that imparts the velocity to the electronics, thus giving them energy.

Accelerating Voltage

In various electron beam instruments and x-ray generators, the difference in potential between the filament (cathode) and the anode, causing acceleration of the electrons by 2–30 keV. See also *depth of penetration* and *resolution*.

Acceleration Period

In cavitation and liquid impingement erosion, the stage following the incubation period, during which the erosion rate increases from near zero to a maximum value.

Accelerator

A material that, when mixed with a catalyst or a resin, speeds up the chemical reaction between the catalyst and the resin (usually in the polymerizing of resins or vulcanization of rubbers). Also called promoter.

Acceptable Quality Level

(1) The lowest-quality level a supplier is permitted to present continually for acceptance. (2) The maximum percentage of defects or number of defective parts considered to be an acceptable average for a given process or technique.

Acceptable Weld

A weld that meets all the requirements and the acceptance criteria prescribed by the welding specifications.

A

Acceptance Test

A test, or series of tests, conducted by the procuring agency, or an agent thereof, upon receipt, to determine whether an individual lot of materials conforms to the purchase order or contract or to determine the degree of uniformity of the material supplied by the vendor or both. Compare to preproduction test and qualification test.

Accepted Reference Value

A value that serves as an agreed-on reference for comparison and which is derived as: (1) a theoretical or established value, based on scientific principles, (2) an assigned value, based on experimental work of some national or international standards organization, or (3) a consensus value, based on collaborative experimental work under the auspices of a scientific or engineering group. When the accepted reference value is the theoretical value, it is sometimes referred to as the “true” value.

Acceptor (in Semiconductor)

See *semiconductor*.

Access Hole

A hole or series of holes in successive layers of a multilayer printed circuit board that provide access to the surface of the land in one of the layers of the board.

Accessory Seal

On various types of engines, a seal that is employed for sealing an accessory shaft in the gearbox, such as a shaft for operating an oil pump, a fuel pump, a generator, a starter, or a deoiler.

Accordion

A type of printed circuit connector contact in which the spring is given a Z shape to permit high deflection without causing overstress.

Accumulation Period

See preferred term acceleration period.

Accumulator

An auxiliary cylinder and piston (plunger) mounted on injection molding or blowing machines and used to provide faster molding cycles. In blow molding, the accumulator cylinder is filled (during the time between parison deliveries, or “shots”) with melted plastic coming from the main (primary) extruder. The plastic melt is stored, or *accumulated*, in this auxiliary cylinder until the next shot or parison is required. At that time, the piston in the accumulator cylinder forces the molten plastic into the dies that form the parison.

1. A reversible electrolytic cell in which electricity is stored as chemical energy.
2. A vessel serving as a reservoir for a fluid power source. A gas, often air, would be stored and compressed while a liquid, often water, might be pressurized or not.

Accumulator Metal Alloys

Based on lead with small quantities of tin and other elements used for electrical storage batteries.

Acetal (AC) Copolymers

A family of highly crystalline thermoplastics prepared by copolymerizing trioxane with small amounts of a comonomer that randomly distributes carbon–carbon bonds in the polymer chain. These bonds, as well as hydroxyethyl terminal units, give the acetal copolymers a high degree of thermal stability and resistance to strong alkaline environments.

The copolymers have an excellent balance of properties and processing characteristics. Melt temperature can range from 182°C to 232°C with little effect on part strength. UV-resistant grades (also available in colors), glass-reinforced grades, low-wear grades, and impact-modified grades are standard. Also available are electroplatable and dimensionally stable, low-warpage grades.

Properties

Acetal copolymers have high tensile flexural strength, fatigue resistance, and hardness. Lubricity is excellent. They retain much of their toughness through a broad temperature range and are among the most creep resistant of the crystalline thermoplastics. Moisture absorption is low, permitting molded parts to serve reliably and environments involving humidity changes.

Good electrical properties, combined with high mechanical strength and an Underwriters’ Laboratories electrical rating of 100°C, qualify these materials for electrical applications requiring long-term stability.

Acetal copolymers have excellent resistance to chemicals and solvents. For example, specimens immersed for 12 months at room temperature in various inorganic solutions were unaffected except by strong mineral acids—sulfuric, nitric, and hydrochloric. Continuous contact is not recommended with strong oxidizing agents such as aqueous solutions containing high concentrations of hypochlorite ions. Solutions of 10% ammonium hydroxide and 10% sodium chloride discolor samples in prolonged immersion, but physical mechanical properties are not significantly changed. Most organic reagents tested have no effect, nor do mineral oil, motor oil, or brake fluids. Resistance to strong alkalis is essentially good; specimens immersed in boiling 50% sodium hydroxide solution and other strong bases for many months showed no property changes.

Strength of acetal copolymer is only slightly reduced after aging for 1 year in air at 116°C. Impact strength holds constant the first 6 months and falls off about one-third during the next 6-month period. Aging in air at 82°C for 2 years has little or no effect on properties, and immersion for 1 year in 82°C water leaves most properties virtually unchanged. Samples tested in boiling water retain nearly original tensile strength after 9 months.

The Creep-modulus curve of acetal copolymer under load shows a linear decrease on a log–log scale, typical of many plastics. Acetal springs lose over 50% of spring force after 1000 h and 60% in 10,000 h. The same spring loses 66% of its force after 100,000 h (about 11 years) under load.

Plastic springs are best used in applications where they generate a force at a specified deflection for limited time but otherwise remain relaxed. Ideally, spring should undergo occasional deflections where they have time to recover, at less than 50% design strain. Recovery time should be at least equal to time under load.

Application

Industrial and automotive applications of acetal copolymer include gears, cams, bushings, clips, lugs, door handles, window cranks, housings, and seat-belt components. Plumbing products such as valves, valve stems, pumps, faucets, and impellers utilize the lubricity and corrosion and hot water resistance of the copolymer. Mechanical components that require dimensional stability, such as watch gears, conveyor links, aerosols, and mechanical pen and pencil parts, or other uses applications for the FDA-approved grades include milk pumps, coffee spigots, filter housings, and food conveyors. Parts that require greater load-bearing stability at elevated temperatures, such as cams, gears, television tuner arms, and automotive underhood components, are molded from glass fiber-reinforced grades.

More costly acetal copolymer has excellent load-bearing characteristics for long-lasting plastic springs. To boost resin performance, engineers use fillers, reinforcing fibers, and additives. Although there are automotive uses for large fiber-reinforced composite leaf springs, unfilled resins are the better candidates for small springs. Glass fibers increase stiffness and strength, but they also limit deflection. And impact modifiers reduce modulus and make plastics more flexible but decrease creep resistance.

Acetal (AC) Homopolymers

Highly crystalline linear polymers formed by polymerizing formaldehyde and capping it with acetate and groups.

The homopolymers are available in several viscosity ranges that meet a variety of processing and end-use needs. The higher-viscosity materials are generally used for extrusions and for molded parts requiring maximum toughness; the lower-viscosity grades are used for injection molding. Elastomer-modified grades offer greatly improved toughness.

Properties

Acetal homopolymer resins have high tensile strength, stiffness, resilience, printing endurance, and moderate toughness under repeated impact. Some tough grades can deliver up to seven times greater toughness than unmodified acetal in Izod impact tests and up to 30 times greater toughness as measured by Gardner impact tests (Table A.2).

Homopolymer acetals have high resistance to organic solvents, excellent dimensional stability, a low coefficient of friction, and outstanding abrasion resistance among thermoplastics. The general-purpose resins can be used over a wide range of environmental conditions; special, UV-stabilized grades are recommended for applications requiring long-term exposure to weathering. However, prolonged exposure to strong acids and bases outside the range of pH 4–9 is not recommended.

Acetal homopolymer has the highest fatigue endurance of any unfilled commercial thermoplastic. Under completely reversed tensile and compressive stress, and with 100% relative humidity (at 73°F), fatigue endurance limit is 30.9 MPa at 10^6 cycles. Resistance to creep is excellent. Moisture, lubricants, and solvents including gasoline and gasohol have little effect on this property, which is important in parts incorporating self-threading screws or interference fits.

The low friction and good wear resistance of acetals against metals make these resins suitable for use in cams and gears having internal bearings. The coefficient of friction (nonlubricated) on steel in a

A

rotating thrust washer test is 0.1–0.3, depending on pressure; little variation occurs from 22.8°C to 121°C. For even lower friction and wear, polytetrafluoroethylene fiber-filled and chemically lubricated formulations are available.

Properties of low moisture absorption, excellent creep resistance, and height deflection temperature suit acetal homopolymer or close-tolerance, high-performance parts.

Applications

Automotive applications of acetal homopolymer resins include fuel-system and seat-belt components, steering columns, window-support brackets, and handles. Typical plumbing applications that have replaced brass or zinc components are showerheads, ball cocks, faucet cartridges, and various fittings. Consumer items include quality toys, garden sprayers, stereo cassette parts, butane lighter bodies, zippers, and telephone components. Industrial applications of acetal homopolymer include couplings, pump impellers, conveyor plates, gears, sprockets, and springs.

Acetal (AC) Resins

Thermoplastics (polyformaldehyde and polyoxymethylene resins) produced by the addition polymerization of aldehydes by means of the carbonyl function, yielding unbranched polyoxymethylene chains of great length. The acetal resins, among the strongest and stiffest of all thermoplastics, are also characterized by good fatigue life, resilience, low moisture sensitivity, high solvent and chemical resistance, and good electrical properties. They may be processed by conventional injection molding and extrusion techniques and fabricated by welding methods used for other plastics.

Processing Acetals

Acetal resin can be molded in standard injection molding equipment at conventional production rates. The processing temperature is around 204°C. Satisfactory performance has been demonstrated in full-automatic injection machines using multicavity molds. Successful commercial moldings point up the ability of the material to be molded to form large-area parts with thin sections, heavy parts with thick sections, parts requiring glossy surfaces or different surface textures, parts requiring close tolerances, parts with undercuts for snap fits, parts requiring metal inserts, and parts requiring no flash. It can also be extruded as rod, tubing, sheeting, jacketing, wire coating, or shapes on standard commercial equipment. Extrusion temperatures are in the range of 199°C–204°C.

Generally, the same equipment and techniques for blow molding other thermoplastics work with acetal resin. Both thin-wall and thick-wall containers (aerosol type) can be produced in many shapes and surface textures.

Various sheet-forming techniques including vacuum, pressure, and matched mold have been successfully used with acetal resins.

Fabrication

Acetal resin is easy to machine (equal to or better than free-cutting brass) on standard production machine shop equipment. It can be sawed, drilled, turned, milled, shaped, reamed, threaded and tapped, blanked and punched, filed, sanded, and polished.

The material is easy to join and offers wide latitude in the choice of fast, economical methods of assembly. Integral bonds of acetal-to-acetal can be performed by welding with a heated metal surface,

hot gas, hot wire, or spin-welding techniques. High-strength joints result from standard mechanical joining methods such as snap fits, interference or press fits, rivets, nailing, heading, threads, or self-tapping screws. Where low joint strengths are acceptable, several commercial adhesives can be used for bonding acetal to itself and other substrates.

Acetyl resin can be painted successfully with certain commercial paints and lacquers, using ordinary spraying equipment and a special surface treatment or followed by a baked topcoat. Successful first surface metalizing has been accomplished with conventional equipment and standard techniques for application of such coatings. Direct printing, process printing, and roll-leaf stamping (hot stamping) can be used for printing on acetyl resin. Baking at elevated temperatures is required for good adhesion of the ink in direct and screen-process printing. In hot stamping, the heated die provides the elevated temperature. Printing produced by these processes resists abrasion and listing by cellophane adhesive tape.

Acetal Plastics

Acetals are independent structural units or a part of certain biological and commercial polymers, and acetal resins are highly crystallized plastics based on formaldehyde polymerization technology. These engineering resins are strong, rigid, and have good moisture, heat, and solvent resistance.

Acetals were specially developed to compete with zinc and aluminum castings. The natural acetal resin is translucent white and can be readily colored with a high sparkle and brilliance. There are two basic types—homopolymer (Delrin) and copolymer (Celcon). In general, the homopolymers are harder, more rigid, have a higher tensile flexural and fatigue strength, but lower elongation; however, they have a higher melting point. Some high-molecular-weight homopolymer grades are extremely tough and have higher elongation than the copolymers. Homopolymer grades are available that are modified for improved hydrolysis resistance to 82°C, similar to copolymer materials.

The copolymers remain stable and long-term, high-temperature service and offer exceptional resistance to the effects of immersion in water at high temperatures. Neither of the types resists strong acids, and the copolymer is virtually unaffected by strong bases. Both types are available in a wide range of melt-flow grades, but the copolymers process more easily and faster than the conventional homopolymer grades.

Both the homopolymers and copolymers are available in several unmodified and glass fiber-reinforced injection molding grades. Both are available in polytetrafluoroethylene or silicone-filled grades, and the homopolymer is available in chemically lubricated low-friction formulations.

The acetals are also available in extruded rod and slab form for machine parts. Property data listed in Table A.2 applied to the general-purpose injection molding and extrusion grade of Delrin 500 and to Celcon M00.

Acetals are among the strongest and stiffest of the thermoplastics. Their tensile strength range is from 54.4 to 92.5 MPa, tensile modulus is about 3400 MPa, and fatigue strength at room temperature is about 34 MPa. Acetals are also among the best in creep resistance. This combined with low moisture absorption (less than 0.4%) gives them excellent dimensional stability. They are useful for continuous service up to about 104°C.

Injection-molding powders and extrusion powders are the most frequently used forms of the material. Sheets, rods, tubes, and pipe are also available. Colorability is excellent.

The range of desirable design properties and processing techniques provides outstanding design freedom in the areas (1) style (color, shape, surface texture, and decoration), (2) weight reduction, (3) assembly techniques, and (4) one-piece multifunctional parts (e.g., combined gear, cam, bearing, and shaft).

Acetic Acid

Also known as ethanoic acid. A colorless, corrosive liquid of pungent odor and composition is $\text{CH}_3 \cdot \text{COOH}$ having a wide variety of industrial uses as a reagent, solvent, and esterifier. A carboxylic acid, it is employed as a weak acid for etching and for soldering, in stain removers and bleaches; as a preservative, in photographic chemicals, for the manufacture of cellulose acetate and vinyl acetate; as a solvent for essential oils, resins, and gums; and as a precipitant for latex, in tanning leather, and in making artificial flavors. Acetic acid is found in the juices of many fruits and, in combination, in the stems or woody parts of plants. It is the active principle in vinegar, giving it the characteristic sour taste, acid flavor, and pungent odor. It is made commercially by oxidation of acetaldehyde (in the presence of manganese, cobalt, or copper acetate), butane, or naphtha. Its specific gravity is 1.049, its boiling point is 118°C , and it becomes a colorless solid below 16.6°C .

Acetone

An important industrial solvent, used in the manufacture of lacquers, plastics, smokeless powder, for dewaxing lubricating oils, for dissolving acetylene for storage, for dyeing cotton with aniline black, and as a raw material in the manufacture of other chemicals. It is a colorless, flammable liquid with a mint-like odor and is soluble in water and in ether. The composition is $\text{CH}_3 \cdot \text{CO} \cdot \text{CH}_3$, specific gravity 0.790, boiling point 56°C , and solidification point -94°C . Acetone is mainly produced as a by-product in the cleavage of cumene hydroperoxide into phenol. A secondary route is by catalytic dehydrogenation of isopropyl alcohol.

Synthetic methyl acetone is a mixture of about 50% acetone, 30 methyl acetate, and 20 methanol, used in lacquers, paint removers, and for coagulating latex. Dihydroxyacetone, a colorless crystalline solid produced from glycerin by sorbose bacteria reaction, is used in cosmetics, and in preparing foodstuff emulsions, plasticizers, and alkyd resins. It is soluble in water and alcohol.

Acetylene

A fuel gas, C_2H_2 , colorless, a flammable gas with a garlic-like odor. Under compressed conditions, it is highly explosive.

Acetylene cannot be compressed to more than about 2 atm, so it is commonly stored in cylinders, which are packed with a suitable porous material such as carbon or kapok and then filled with acetone. The acetone is capable of absorbing about 25 times its own volume of acetylene for every atmosphere increase in pressure.

With its intense heat and controllability, the oxyacetylene flame can be used for many different welding and cutting operations including hard facing, brazing, beveling, gouging, and scarfing. The heating capability of acetylene also can be utilized in the bending, straightening, forming, hardening, softening, and strengthening of metals.

Achromatic

Free of color. A lens or objective is achromatic when corrected for longitudinal chromatic aberration for two colors. See also *achromatic objective*.

Achromatic Lens

A lens that is corrected for chromatic aberration so that its tendency to refract light differently as a function of wavelength is minimized. See also *achromatic* and *apochromatic lens*.

Achromatic Objective

Objectives are achromatic when corrected chromatically for two colors, generally red and green, and spherically for light of one color, usually in the yellow-green portion of the spectrum.

Acicular Alpha (Titanium)

A product of nucleation and growth from β to the lower temperature allotrope α phase. It may have a needlelike appearance and may have needle, lenticular, or flattened bar morphology in three dimensions.

Acicular Ferrite

A highly substructured nonequiaxed ferrite formed upon continuous cooling by a mix diffusion and shear mode of transformation that begins at a temperature slightly higher than the transformation temperature range for upper bainite. It is distinguished from bainite in that it has a limited amount of carbon available; thus, there is only a small amount of carbide present.

Acicular Ferrite Steels

Ultralow carbon ($<0.08\%$) steels having a microstructure consisting of either acicular ferrite (low-carbon bainite) or a mixture of acicular and equiaxed ferrite.

Acicular Powder

A powder composed of needle or sliver-like particles.

Acid

A chemical substance that yields hydrogen ions (H^+) when dissolved in water. If it produces hydroxyl ions, (OH^-), it is termed "alkaline." Compare with base and pH. In a metallurgical context, the term indicates processes in which the environmental conditions such as the furnace refractory lining and slags, which contain a high percentage of silica and minerals, are acidic as opposed to basic. Siliceous refractories, for example, are acidic.

Acid Acceptor

A compound that acts as a stabilizer by chemically combining with acid that may be initially present in minute quantities in a plastic or that may be formed by the decomposition of the resin.

Acid Bottom and Lining

The inner bottom and lining of a melting furnace, consisting of materials like sand, siliceous rock, or silica brick that give an acid reaction at the operating temperature.

Acid Cleaning

The use of acid to dissolve undesirable materials, such as scale, from a metal surface. Dissolution of the underlying metal is intended to be

A

minimal. Also termed “pickling” although this term also includes the use of alkaline solvents.

Acid Copper

(1) Copper electrodeposited from an acid solution of a copper salt, usually copper sulfate. (2) The solution referred to in (1).

Acid Core Solder

See *cored solder*.

Acid Dip

The use of acid solutions to clean components. The term tends to imply an intent to remove slight tarnishing rather than severe scale, that is, a less aggressive attack than implied by acid cleaning.

Acid Embrittlement

Any embrittlement resulting from contact with acid, for example, during pickling. It is a form of hydrogen embrittlement caused when hydrogen, released by the chemical reaction with the acid, enters the metal in quantities large enough to cause damage such as cracking or a tendency toward a nonductile failure during forming operations.

Acid Etching

The use of acid to dissolve, within controlled limits, the surface of the metal. It is used in metallography to reveal details of the microstructure of a metal, printing to provide a release effect or in industry to prepare a metal surface for treatments such as painting or electroplating.

Acid Extraction

Removal of phases by dissolution of the matrix metal in an acid. See also *extraction*.

Acid Lining

A refractory furnace lining, usually silica, which produces an acid reaction with the charge.

Acid Process

A steelmaking method using an acid refractory-lined furnace. Neither sulfur nor phosphorous is removed.

Acid Rain

Atmospheric precipitation with a pH below 5.6–5.7. Burning of fossil fuels for heat and power is the major factor in the generation of oxides of nitrogen and sulfur, which are converted into nitric and sulfuric acids washed down in the rain. See also *atmospheric corrosion*.

Acid Refractory

Siliceous ceramic materials of a high melting temperature, such as silica brick, used for metallurgical furnace linings. Compare with basic refractories. See also *refractories*.

Acid Steel

Steel melted in a furnace with an acid bottom and lining and under a slag containing an excess of an acid substance such as silica.

A_{cm} , A_1 , A_3 , A_4

Same as $A_{e_{cm}}$, A_{e_1} , A_{e_3} , A_{e_4} .

Acoustic Emission

A measure of integrity of a material, as determined by sound emission on a material, is stressed. Ideally, emissions can be correlated with defects and/or incipient failure.

Acoustic Fatigue

Fatigue induced by atmospheric vibration associated with noise, air turbulence, or vortex shedding. Also called sonic fatigue.

Acrylic Plastics

Acrylic plastics comprise a broad array of polymers and copolymers in which the major monomeric constituents belong to two families of esters-acrylates and methacrylates. These are used singly or in combination. Hard, clear acrylic sheet is made from methyl methacrylate, whereas molding and extrusion pellets are made from methyl methacrylate copolymerized with small percentages of other acrylates or methacrylates.

The resins produced may be in the form of casting syrups (for cast sheet) or pellets for molding and extrusion. The latter are made either in bulk (continuous solution polymerization), followed by extrusion and pelletizing, or continuously by polymerization in an extruder in which unconverted monomer under reduced pressure and recovered for recycling.

The most widely used acrylic plastics are based on polymers of methyl methacrylate. This primary constituent may be modified by copolymerizing or blending with other acrylic monomers or modifiers to obtain a variety of properties. Although acrylic polymers based on monomers other than methyl methacrylate have been investigated, they are not as important as commercial plastics and are generally confined to uses in fibers, rubbers, motor oil additives, and other special products.

Standard Acrylics

Poly(methyl methacrylate), the polymerized methyl ester of methacrylic acid, is thermoplastic. The method of polymerization may be varied to achieve specific physical properties, or the monomer may be combined with other components. Sheet materials may be prepared by casting the monomer in bulk. Suspension polymerization of the monomeric ester may be used to prepare molding powders.

Conventional poly(methyl methacrylate) is amorphous; however, reports have been published of methyl methacrylate polymers of regular configuration, which are susceptible to crystallization. Both the amorphous and crystalline forms of such crystallization-susceptible polymers possess physical properties that are different from those of the conventional polymer and suggest new applications.

Service Properties

Acrylic thermoplastics are known for their outstanding weatherability. They are available in cast sheet, rod, and tube, extruded

sheet and film, and compounds for injection molding and extrusion. They are also characterized by good impact strength, formability, and excellent resistance to sunlight, weather, and most chemicals. Maximum service temperature of heat-resistant grades is about 200°F. Standard grades are rated as slow burning, but a special self-extinguishing grade of sheet is available. Although acrylic plastic weighs less than half as much as glass, it has many times greater impact resistance. As a thermal insulator, it is approximately 20% better than glass. It is tasteless and odorless.

When poly(methyl methacrylate) is manufactured with scrupulous care, excellent optical properties are obtained. Light transmission is 92%; colorants produce a full spectrum of transparent, translucent, or opaque colors. Most colors can be formulated for long-term outdoor durability. Acrylics are normally formulated to filter UV energy and the 360 nm and lower band. Because of its excellent transparency and favorable index of refraction, acrylic plastic is often used in the manufacture of optical lenses. Superior dimensional stability makes it practical to produce precision lenses by injection molding techniques.

In chemical resistance, poly(methyl methacrylate) is virtually unaffected by water, alkalies, weak acids, most inorganic solutions, mineral and animal oils, and low concentrations of alcohol. Oxidizing acids affect the material only at high concentrations. It is also virtually unaffected by paraffinic and olefinic hydrocarbons, amines, alkyl monohalides, and esters containing more than 10 carbon atoms. Lower esters, aromatic hydrocarbons, phenols, aryl halides, aliphatic acids, and alkyl polyhalides usually have a solvent action. Acrylic sheet and moldings are attacked, however, by chlorinated and aromatic hydrocarbons, esters, and ketones.

Mechanical properties of acrylics are high for short-term loading. However, for long-term service, tensile stresses must be limited to 1500 psi to avoid crazing or surface cracking.

The moderate impact resistance of standard formulations is maintained even under conditions of extreme cold. High-impact grades have considerably higher impact strength than standard grades at room temperature, but impact strength decreases as temperature drops. Special formulations ensure compliance with Underwriters' Laboratories standards for bullet resistance.

Although acrylic plastics are among the most scratch resistant of the thermoplastics, normal maintenance and cleaning operations scratch and abrade them. Special abrasive-resistant sheet is available that has the same optical and impact properties as standard grades.

Toughness of acrylic sheet, as measured by resistance to crack propagation, can be improved several folds by inducing molecular orientation during forming. Jet aircraft cabin windows, for example, are made from oriented acrylic sheet.

Transparency, gloss, and dimensional stability of acrylics are virtually unaffected by years of exposure to the elements, salt spray, or corrosive atmospheres. These materials withstand exposure to light from fluorescent lamps without darkening or deteriorating. They ultimately discolor, however, when exposed to high-intensity UV light below 265 nm. Special formulations resist UV emission from light sources such as mercury-vapor and sodium-vapor lamps.

Product Forms

Cell-cast sheet is produced in several sizes and thicknesses. The larger sheets available are 120 × 144 in., thicknesses from 0.0302 to 4.25 in. Continuous-cast material is supplied as flat sheet to 1/2 in. thick, in widths to 9 ft. Acrylic sheet cast by the continuous process (between stainless steel belts) is more uniform in thickness than cell-cast sheet. Cell-cast sheet, on the other hand, which is cast between glass plates, has superior optical properties and surface quality. Also, cell-cast sheet is available in a greater variety of colors

and compositions. Cast acrylic sheet is supplied in general-purpose grades and in UV-absorbing, mirrored, super-thermoformable, and cementable grades, and with various surface finishes. Sheets are available in transparent, translucent, and opaque colors.

Acrylic film is available in 2, 3, and 6 mil thicknesses, in clear form and in colors. It is supplied in rolls to 60 in. wide, principally for use as a protective laminated cover over other plastic materials.

Injection molding and extrusion compounds are available in both standard and high-molecular-weight grades. Property differences between the two formulations are principally in flow and heat resistance. Higher-molecular-weight resins have lower melt-flow rates and greater hot strength joint processing. Lower-molecular-weight grades flow more readily and are designed for making complex parts and hard to fill; see Table A.3.

Fabrication Characteristics

When heated to a pliable state, acrylic sheet can be formed to almost any shape. The forming operation is usually carried out at about 292°F–340°F. Aircraft canopies, for example, are usually made by differential air pressure, either with or without balls. Such canopies have been made from (1) monolithic sheet stock; (2) laminates of two layers of acrylic, bonded by a layer of polyvinyl butyral; and (3) stretched monolithic sheet. Irregular shapes, such as sign faces, lighting fixtures, or boxes, can be made by positive pressure forming, using molds.

Residual strains caused by forming are minimized by annealing, which also brings cemented joints to full strength. Cementing can be readily accomplished by using either solvent or polymerizable cements.

Acrylic plastic can be sawed, drilled, and machined like wood or soft metals. Saws should be hollow ground or have set teeth. Slow feed and coolant will prevent overheating. Drilling can be done with conventional metal-cutting drills. Routing requires high-speed cutters to prevent chipping. Finished parts can be sanded, and sanded surfaces can be polished with a high-speed buffing wheel. Cleaning should be by soap or detergent and water, not by solvent-type cleaners.

Acrylic molding powder may be used for injection, extrusion, or compression molding. The material is available on several grades, with a varying balance of flow characteristics and heat resistance. Acrylics give molded parts of excellent dimensional stability. Precise contours and sharp angles, important in such applications as lenses, are achieved without difficulty, and this accuracy of molding can be maintained throughout large production runs.

Since dirt, lint, and dust detract from the excellent clarity of acrylics, careful handling and storage of the molding powder are extremely important.

Applications

In merchandising, acrylic sheet has become a major sign material for internally lighted faces and letters, particularly for outdoor use where resistance to sunlight and weathering is important. In addition, acrylics are used for counter dividers, display fixtures and cases, transparent demonstration models of household appliances and industrial machines, and vending machine cases.

The ability of acrylics to resist breakage and corrosion and to transmit and diffuse light efficiently has led to many industrial and architectural applications. Industrial window glazing, safety shields, inspection windows, machine covers, and pump components are some of the uses commonly found in plants and factories. Acrylics are employed to good advantage as the diffusing medium in lighting fixtures and large luminous ceiling areas. Dome skylights form

from acrylic sheet are an increasingly popular means of admitting daylight to industrial, commercial, and public buildings even to private homes.

Shower enclosures and deeply formed components such as top-shower units, which are subsequently backed with glass fiber-reinforced polyester and decorated partitions, are other typical applications. A large volume of the material is used for curved and flat windshields or pleasure boats, both in board and outboard types.

Acrylic sheet is the standard transparent material for aircraft canopies, windows, instrument panels, and searchlight and landing light covers. To meet the increasingly severe service requirements of pressurized jet aircraft, new grades of acrylic have been developed that have improved resistance to heat and crazing. The stretching technique has made possible enhanced resistance to both crazing and shattering. Large sheets, edge lighted, are used as radar plotting boards and shipboard and ground-control stations.

In molded form, acrylics are used extensively for automotive parts, such as taillight and stoplight lenses, medallions, dials, instrument panels, and signal lights. The beauty and durability of molded

acrylic products have led to their wide use for nameplates, control knobs, dials, and handles on all types of appliances. Acrylic molding powder is also used for the manufacture of pen and pencil barrels, hairbrush backs, watch and jewelry cases, and other accessories. Large-section moldings, such as covers for fluorescent streetlights, coin-operated phonograph panels, and fruit juice dispenser bowls, are being molded from acrylic powder. The extrusion of acrylic sheet from molding powder is particularly effective in the production of thin sheeting for use in such applications as signs, lighting, glazing, and partitions.

The transparency, strength, lightweight, and edge-lighting characteristics of acrylics have led to applications in the fields of hospital equipment, medical examination instruments, and orthopedic devices. The use of acrylic polymers in the preparation of dentures is an established practice. Contact lenses are also made of acrylics. The embedment of normal and pathological tissues in acrylic for preservation and instructional use is an accepted technique. This has been extended to include embedment of industrial machine parts, and sales aids, and the preparation of various types of home decorative articles.

High-Impact Acrylics

High-impact acrylic molding powder is used in large-volume, general use. It is used where toughness greater than that found in the standard acrylics is desired. Other advantages include resistance to staining, high surface gloss, dimensional stability, chemical resistance, and stiffness, and they provide the same transparency and weatherability as the conventional acrylics.

High-impact acrylic is off-white and nearly opaque in its natural state and can be produced in a wide range of opaque colors. Several grades are available to meet requirements for different combinations of properties. Various members of the family have Izod impact strength from about 0.5 to as high as 4 ft lb/in. notch. Other mechanical properties are similar to those of conventional acrylics.

High-impact acrylics are used for hard service applications, such as women's thin-style shoe heels and housings, ranging from electric razors to outboard motors, piano and organ keys, and beverage vending machine housings and canisters—in short, applications where toughness, chemical resistance, dimensional stability, stiffness, resistance to staining, lack of unpleasant odor or taste, and high surface gloss are required.

Acrylic Resins

Colorless, highly transparent, thermoplastic, synthetic resins made by the polymerization of acrylic derivatives, chiefly from the esters of acrylic acid, $\text{CH}_2=\text{CH}\cdot\text{COOH}$, and methacrylic acid, $\text{CH}_2=\text{C}(\text{CH}_3)\cdot\text{COOH}$, ethyl acrylate, and methyl acrylate.

The resins vary from soft, sticky semisolids to hard, brittle solids, depending upon the constitution of the monomers and upon the polymerization. They are used for adhesives, protective coatings, finishes, laminated glass, transparent structural sheet, and molded products. Acrylic resins or acrylate resins are stable and resistant to chemicals. They do not cloud or fade in light when used as laminating material in glass and are used as air-curing adhesives to seal glass to metals or wood. Water-based acrylics are used for the formulation of calks and sealants. They have better adhesion and weather resistance than butyl rubbers and dry more quickly. The sealants usually contain about 80% solids.

Lucite is methyl methacrylate of DuPont, marketed as molding powder and in rods, tubes, and cast and molded sheets. Plexiglas, of Rohm and Haas Company, is transparent methyl methacrylate in sheets and rods. This plastic is used for aircraft windows. Plexiglas V is for injection molding, while Plexiglas VM is a molding powder to resist heat distortion to 174°F (79°C). Korad films, from Polymer Extruded Products, are weatherable, wood grain, acrylic laminating films for outdoor window and door profiles and for adhesive-free bonding to polypropylene sheet for thermoformed products. Acumer 3000, a water-treatment acrylic polymer from Rohm and Haas Company, controls silica and prevents formation of magnesium–silicate scale.

The Acryloid resins, of Rohm and Haas Company, are acrylic copolymer solid resins, and the Acrysol resins are solutions for coatings. Plexene M, of the same company, is a styrene–acrylic resin for injection molding.

Acrylonitrile

A monomer with the structure $(\text{CH}_2=\text{CHCN})$. It is most useful in copolymers. Its copolymer with butadiene is nitrile rubber; acrylonitrile–butadiene copolymers with styrene are tougher than polystyrene. Acrylonitrile is also used as a synthetic fiber and as a chemical intermediate. Also called vinyl cyanide and propene nitrile.

It is used as a liquid in insecticides and for producing plastics and other chemicals. It is made by the addition of hydrocyanic acid to acetylene, by using propylene as the starter and reacting with ammonia or from petroleum. Acrylonitrile fiber, originally developed in Germany as a textile staple fiber and as a monofilament for screens in weaving, and known as Redon, has good dimensional stability and high dielectric strength and is resistant to water and solvents.

Orlon, of DuPont, is a polymerized acrylonitrile fiber. It is nearly as strong as nylon and has a softer feel. It can be crimped to facilitate spinning with wool. It is used for clothing textiles and for filter fabrics. *Dynel*, of Union Carbide Corp., is an acrylonitrile–vinyl chloride copolymer staple fiber. It produces textiles with a warmth and feel like those of wool. It has good strength, is resilient, dyes easily, and is mothproof. *Verel*, of Eastman Chemical Company, is a similar acrylic fiber produced from acrylonitrile and vinylidene chloride, and *Creslan*, of American Cyanamid Company, called *Exlan* in Japan, is an acrylic fiber. *Acrilan*, of Monsanto, is a similar textile fiber and is an acrylonitrile–vinyl acetate copolymer. Acrylonitrile–styrene is a copolymer for injection molding and extruding that produces rigid thermoplastic parts of a higher tensile strength than those of the methacrylates and has good dimensional stability and scratch resistance. *Saran F-120*, of Dow Chemical Company, is a similar material.

Acrylonitrile–Butadiene–Styrene (ABS)

Acrylonitrile–butadiene–styrene (ABS) are three thermoplastic monomers.

Actinic

Of light, characterized by radiation that causes chemical changes, for example, the effect of light on photographic emulsions. Blue and ultraviolet are the most actinic regions of the spectrum.

Actinide Metals

The group of radioactive elements of atomic numbers 89–103 of the periodic system—namely, thorium, protactinium, uranium, neptunium, plutonium, americium, curium, berkelium, californium, einsteinium, fermium, mendelevium, nobelium, and lawrencium.

Actinium

A radioactive metallic element with no significant commercial application.

Activated

Any material treated in some way to enhance its response to its environment.

Activated Alumina

Partly dehydrated aluminum hydroxide. It is used as a desiccant and catalyst.

Activated Charcoal

A nearly chemically pure amorphous carbon made by carbonizing and treating dense material such as coconut shells, peach pits, or

A

hardwood. When made from coal, or in the chemical industry, it is more usually called activated carbon or filter carbon.

This carbon-rich material is produced by heating carbonaceous material in the absence of oxygen. It is used to absorb contaminants. Furthermore, it is used as an adsorbent material for gas masks, for cigarette filters, and for purifying acids, recovering solvents, and decolorizing liquids. Activated carbon woven into garments protects members of the armed forces from chemical warfare. Garments with superactivated carbon are lighter in weight and much more absorbent.

Activated Rosin Flux

A rosin- or resin-base flux containing an additive that increases wetting by the solder.

Activated Sintering

The use of additives, such as chemical additions to the powder or additions to the sintering atmosphere, to improve the densification rate. See *sintering*.

Activating

A treatment that renders nonconductive material receptive to electroless deposition. Also called seeding, catalyzing, and sensitizing, all of which are not preferred terms.

Activation

(1) The changing of a passive surface of a metal to a chemically active state. In contrast with *passivation*. (2) The (usually) chemical process of making a surface more receptive to bonding with a coating or an encapsulating material.

Activation Analysis

A method of chemical analysis based on the detection of characteristic radionuclides following nuclear bombardment. See also *neutron activation analysis*.

Activation Energy

The additional energy required for initiating a metallurgical reaction or physical process—for example, plastic flow, diffusion, chemical reaction. The activation energy may be calculated from the slope of the line obtained by plotting the natural log of the reaction rate versus the reciprocal of the absolute temperature.

Activator

The additive used in activated sintering, also called a dopant.

Active

The negative direction of *electrode potential*. Also used to describe corrosion and its associated potential range when an electrode potential is more negative than an adjacent depressed corrosion rate (passive) range.

Active Area

In electronic packaging, the internal area of a package bottom, usually a cavity, is used for substrate attachment. The term is applied preferably to package cases of all-metal construction (as opposed to glass or ceramic).

Active Components

Electronic components, such as transistors, diodes, electron tubes, and thyristors, which can operate applied electrical signal in such a way as to change its basic characteristics, for example, rectification, amplification, and switching.

Active Devices

Parts of a circuit that are capable of amplification, usually silicon semiconductor devices. Transistors, for instance, are active devices. Components that cannot amplify are passive—for example, resistors and capacitors.

Active Mass

The molecular concentration.

Active Material

Reacting, or capable of reacting, with its environment.

Actuators

Actuators and materials play a key role in developing advanced precision engineering. The breakthroughs in this field are closely related to the development of various types of actuators and related materials. The successes of piezoelectric ceramics and ceramic actuators have, for instance, the propagating-wave type ultrasonic motor that produces precise rotational displacements has been used in autofocusing movie cameras and VCRs. Multimorph ceramic actuators prepared from electrostrictive $\text{Pb}(\text{Mg}_{1/3}\text{Nb}_{2/3})\text{O}_3$ ceramics are used as deformable mirrors to correct image distortions from atmospheric effects. The likelihood that the range of applications and demand for actuators will grow actively has stimulated intensive research on the piezoelectric ceramics.

Each kind of actuator has its own advantages and drawbacks, so their selection and optimization should be determined by the requirements of the application.

Piezoelectric/electrostrictive ceramics are widely used in many different types of sensing–actuating devices. This is particularly true for the whole family of micro- and macropiezoelectric ceramic actuators. Various types of ceramic actuators have been developed for different applications. From a structural point of view, ceramic actuators are classified as unimorph, bimorph, moonie, cymbal, and rainbow monomorph benders.

Another device developed to increase the force–displacement performance of a piezoelectric actuator is the rainbow, a monolithic monomorph that is produced from the conventional, high-lead piezoelectric ceramic disk that has one surface reduced to a nonpiezoelectric phase by a high-temperature, chemical reduction reaction.

The photostrictive actuator is another type of bimorph application. The photostrictive behavior results from a combined photovoltaic effect in a piezoelectric effect.

There is also increasing interest in electrostrictive ceramic actuators because electrostrictive ceramics do not contain ferroelectric domains, so that they can return to their original dimensions immediately, when the external electric field is reduced to zero. Therefore, the advantages of an electrostrictive actuator are the near absence of hysteresis and lack of aging behavior.

Piezoelectric/electrostrictive ceramics, magnetostrictive materials, and ferroelastic shape memory alloys are all used for actuators. However, different classes of ceramic actuators require somewhat different materials. In general, an ideal actuating material should exhibit a large stroke, high recovery force, and superior dynamic response.

Addition Agent

(1) A substance added to a solution for the purpose of altering or controlling a process or modifying its characteristics. Examples are wetting agents in acid pickles; brighteners or antipitting agents in plating solutions, to improve luster; or materials added to pickling baths to inhibit pitting. (2) Any material added to a charge of molten metal in a bath or ladle to bring the alloy to specifications.

Addition Polymerization

A chemical reaction in which simple molecules (monomers) are linked to each other to form long-chain molecules (polymers) by chain reaction.

Additive

(1) In lubrication, a material added to a lubricant for the purpose of imparting new properties or of enhancing existing properties. Main classes of additives include *anticorrosive*, *antifoam*, *antioxidant*, *antiwear*, *detergent*, *dispersant*, *extreme pressure*, and *viscosity index improver additives*.

(2) In polymer engineering, a substance added to another substance, usually to improve properties, such as plasticizers, initiators, light stabilizers, and flame retardants. See also *filler*.

Additive Process

A process for obtaining conductive patterns by the selective deposition of conductive material on clad or unclad base material. See also *semiadditive process*, *semiattractive process*, and *fully additive process*.

Adhere

To cause two surfaces to be held together by adhesion.

Adherence

In tribology, the physical attachment of material to a surface (either by adhesion or by other means of attachment) that results from the contact of two solid surfaces undergoing relative motion. Adhesive bonding is not a requirement for adherence because mechanism such as mechanical interlocking of asperities can also provide a means for adherence. See also *adhesion (adhesive force)* and *mechanical adhesion*.

Adherend

A body held to another body by an adhesive. See also *substrate*.

Adherend Preparation

See *surface preparation*.

Adhesion

(1) In frictional contacts, the attractive force between adjacent surfaces. In physical chemistry, adhesion denotes the attraction between a solid surface and a second (liquid or solid) phase. This definition is based on the assumption of a reversible equilibrium. In mechanical technology, adhesion is generally irreversible. In railway engineering, adhesion often means friction. (2) Force of attraction between the molecules (or atoms) of two different phases. In contrast with *cohesion*. (3) The state in which two surfaces are held together by interfacial forces, which may consist of valence forces, interlocking action, or both. (4) Bonding of components by means of some glue-like substance in the interface—galling and seizure are appropriate. See also *mechanical adhesion* and *specific adhesion*.

Adhesion Coefficient

See *coefficient of adhesion*.

Adhesion Promoter

A coating applied to a substrate, before it is coated with an adhesive, to improve the adhesion of the substrate. Also called *primer*.

Adhesion Promotion

The chemical process of preparing a surface to provide for a uniform, well-bonded interface.

Adhesive

A substance capable of holding materials together by surface attachment. Adhesive is a general term and includes, among others, cement, glue, mucilage, paste, and mastic. These terms are loosely used interchangeably. Various descriptive adjectives are applied to the term adhesive to indicate certain physical characteristics: *hot-melt adhesives*, *pressure-sensitive adhesives*, *structural adhesives*, *ultraviolet/electron beam-cured adhesives*, and *water-based adhesives*. The characteristics of these five groups of adhesives are summarized in Table A.4. Table A.5 lists the advantages and limitations of the five groups.

Adhesives are characterized by degree of tack, or stickiness, by strength of bond after setting or drying, by rapidity of bonding, and by durability. The strength of bond is inherent in the character of the adhesive itself, particularly in its ability to adhere intimately to the surface to be bonded. Adhesives prepared from organic products are in general subject to disintegration on exposure. The life of an adhesive usually depends upon the stability of the ingredient that gives the holding power, although otherwise good cements of synthetic materials may disintegrate by the oxidation of fillers or materials used to increase tack. Plasticizers usually reduce adhesion. Some fillers such as mineral fibers or walnut-shell flour increase the thixotropy and the strength, while some such as starch increase the tack but also increase the tendency to disintegrate.

TABLE A.4
Characteristics of Various Types of Adhesives

Structural	Hot Melt	Pressure Sensitive	Water Base	Ultraviolet/Electron Beam Cured
Bonds can be stressed to a high proportion of maximum failure load under service environments.	100% solid thermoplastics.	Hold substrates together upon brief application of pressure at room temperature.	Includes adhesives dissolved or dispersed (latex) in water.	100% reactive liquids cured to solids.
Most are thermosets.	Melt sharply to a low-viscosity liquid, which is applied to surface.	Available as organic solvent-base, water-base, or hot-melt systems.	On porous substrates, water is absorbed or evaporated in order to bond.	One substrate must be transparent for UV cure, except when dual-curing adhesives are used (see below).
One- or two-component systems.	Rapid setting, no cure.	Some require extensive compounding (rubber base) to achieve tackiness, whereas others (polyacrylates) do not.	On nonporous substrates, water must be removed prior to bonding.	Some UV-curable formulations are dual curing; a second cure mechanism introduces heat or moisture or eliminates oxygen (anaerobics).
Room- or elevated-temperature cures.	Melt viscosity is an important property.	Available supported (most) or unsupported on a substrate.	Some are bonded following reactivation of dried adhesive film under heat and pressure.	In electron beam (EB) curing, density of material affects penetration.
Wide range of costs.	Nonpressure sensitive and pressure sensitive.	Primarily used in tapes and labels.	Many are based on natural (vegetable or animal) adhesives.	UV/EB-curable formulations have laminating and pressure-sensitive adhesive (PSA) applications.
Various chemical families with varying strengths and flexibilities.	Compounded with additives for tack and wettability.		Nonpressure-sensitive (most) or pressure-sensitive applications.	UV-curable formulations have laminating, PSA, and structural adhesive applications.

TABLE A.5
Advantages and Limitations of Various Types of Adhesives

Structural	Hot Melt	Pressure Sensitive	Water Base	Ultraviolet/Electron Beam Cured
<i>Advantages</i>				
High strength.	100% solids, no solvents.	Labels and tapes have uniform thickness.	Low cost, nonflammable, nonhazardous solvent.	Fast cure (some in 2–60 s).
Capable of resisting loads.	Can bond impervious surfaces.	Permanent tack at room temperature.	Long shelf life.	One-component liquid no mixing, no solvents.
Good elevated-temperature resistance (cross-linked).	Rapid bond formation.	No activation required by heat, water, or solvents.	Easy to apply.	Heat-sensitive substrates can be bonded; cure is “cool.”
Good solvent resistance.	Good gap-filling capability.	Cross-linking of some formulations possible.	Good solvent resistance.	Many are optically clear.
Good creep resistance.	Rigid to flexible bonds.	Soft or firm tapes and labels.	Cross-linking of some formulations possible.	High production rates.
Some available in film form.	Good barrier properties.	Easy to apply.	High-molecular-weight dispersions at high solids content with low viscosity.	Good tensile strength.
<i>Limitations</i>				
Two-component systems require careful proportioning and mixing.	Thermoplastics have limited elevated-temperature resistance.	Many are based on rubbers, requiring compounding.	Poor water resistance.	Equipment expensive.
Some have poor peel strength.	Poor creep resistance.	Poor gap fillers.	Slow drying.	High material cost.
Some are difficult to remove and repair.	Little penetration due to fast viscosity increase upon cooling.	Limited heat resistance.	Tendency to freeze.	UV cures only through transparent materials (or secondary cure required).
Some require heat to cure.	Limited toughness at usable viscosities.		Low strength under loads.	Difficult curing on parts with complex shapes.
Some yield by-products upon cure (condensation polymers).			Poor creep resistance.	Many UV cures have poor weatherability because they continue to absorb UV rays.
			Limited heat resistance.	
			Shrinkage of certain substrates in supported films and tapes.	

From an industrial manufacturing standpoint, the advent of the stealth aircraft and all the structural adhesive bonding it entails has drawn widespread attention to the real capabilities of adhesives. Structural bonding uses adhesives to join load-bearing assemblies. Most often, the assemblies are also subject to severe service conditions. Such adhesives, regardless of chemistry, generally have the following properties:

- Tensile strengths in the 1500–4500 psi range
- Very high impact and peel strength
- Service temperature ranges of about -65°F to 3500°F

If these types of working conditions are expected, then one should give special consideration to proper adhesive selection and durability testing.

Parameters

Innumerable adhesives and adhesive formulations are available today. The selection of the proper type for a specific application can only be made after a complete evaluation of the design, the service requirements, production feasibility, and cost considerations. Usually, such selection is best left to adhesive suppliers. Once they have been given the complete details of the application, they are in the best position to select both the type and specific adhesive formulation.

Types and Forms

Adhesives have been in use since ancient times and are even mentioned in the Bible. The first adhesives were of natural origin, for example, bitumen, fish oil, and tree resins. In more modern times, adhesives were still derived from natural products but were processed before use. These modern natural adhesives include animal-derived (such as blood, gelatin, and casein), vegetable-derived (such as soybean oil and wheat flour), and forest-derived (pine resins and cellulose derivatives) products.

Forms include liquid, paste, powder, and dry film. The commercial adhesives include pastes, glues, pyroxylin cements, rubber cements, latex cement, special cements of chlorinated rubber, synthetic rubbers or synthetic resins, and the natural mucilages.

Joint Design

Bonded joints have four main loading modes:

- Peel loads produced by out-of-plane loads acting on thin substrates.
- Shear stresses produced by tensile, torsional, or pure shear loads on substrates.
- Tensile stresses produced by out-of-plane tensile loads.
- Cleavage loads produced by out-of-plane tensile loads acting on the rigid and thick substrates at the end of the joint.
- Good joint design for substrates and structural adhesives maximizes tension, compression and shear, minimizes peel and cleavage, and increases the bond area—wider is better.

The aim is to design a joint that maintains the adhesive in a state of shear or compression, since bonded joints are strongest under these conditions. Avoid or at least minimize tension, cleavage, and

peel forces. The presence of stresses compromises joint strength and fatigue resistance. It is important to ensure that the adhesive is not the weakest link in the bond. Structural adhesives are known for their relatively poor resistance to peel stresses, and to obtain a maximum bond efficiency joints must be designed to minimize tensile stresses. Potential failure modes for structural adhesives bonding metallic or composite joints include

- Tensile, compressive, or shear failure of the adherends
- Shear or peel in the adhesive
- Shear or peel in a composite near surface plies
- Shear or peel in the resin-rich layer on the composite's surface
- Adhesive failure at the metal/adhesive or composite/adhesive interface

Adhesive failure is a rupture of the adhesive bond, separating the adhesive from the adherend (substrate). Adhesive failure can also be called interfacial failure. Cohesive failure of the adhesive occurs when the load exceeds the inherent adhesive strength. Cohesive failure of the adherend occurs when the load exceeds the adherend strength.

Good bond joint design is critical to the successful use of structural adhesives. Joint designs can include lap/overlap, double lap, butt joint, scarf joint, strap or double strap joint, and a cylindrical joint. The joint design should increase bond strength. Butt joints are best used when stresses are concentrated along the bottom line and perpendicular forces are minimal. Scarf joints are useful for close-fitting parts that allow a large contact area. Lap and offset lap joints are well suited for bonding thin, cross-sectional, rigid parts. In lap joints, the bonded parts are slightly offset. See Figure A.1.

When working with liquid adhesives, a smooth and consistent bead is important to ensure a good bond. Too much or too little adhesive introduces inconsistencies and potential problems. With tape systems, using the right amount of pressure is critical to ensure that the tape adheres completely and fills in any gaps between materials, especially between machine materials.

FIGURE A.1 Good joint design for substrates and structural adhesives maximizes tension, compression, and shear, minimizes peel and cleavage, and increases the bond area—wider is better.

Current and Future Market

Structural adhesives can now be found in a range of industries, including transportation, construction, product assembly, medical device manufacturing, electrical and electronics, and defense. Within these industries, applications can include flanges for doors and enclosures, window/glass attachment, attachment of components, bonding of dissimilar substrates, body/rigid panel attachment, and engine components where vibration absorption is critical.

Classification

Adhesives can recruit into five classifications based on chemical composition. These are summarized in Table A.6.

Natural

These include vegetable- and animal-based adhesives and natural gums. They are inexpensive, easy to apply, and have a long shelf life. They develop tack quickly but provide only low-strength joints. Most are water soluble. They are supplied as liquids or as dry powders to be mixed with water.

Casein-latex type is an exception. It consists of combinations of casein with either natural or synthetic rubber latex. It is used to bond metal to wood for panel construction and to join laminated plastics and linoleum to wood and metal. Except for this type, most natural adhesives are used for bonding paper, cardboard, foil, and light wood.

Synthetic Polymer

The greatest growth in the development and use of organic compound-based adhesives came with the application of synthetically

TABLE A.6
Adhesives Classified by Chemical Composition

	Natural	Thermoplastic	Thermosetting	Elastomeric	Alloys ^a
Types within group	Casein, blood albumin, hide, bone, fish, starch (plain and modified); rosin, shellac, asphalt; inorganic (sodium silicate, litharge-glycerin)	Polyvinyl acetate, polyvinyl alcohol, acrylic, cellulose nitrate, asphalt, oleoresin	Phenolic, resorcinol, phenol-resorcinol, epoxy, epoxyphenolic, urea, melamine, alkyd	Natural rubber, reclaim rubber, grade of butadiene-styrene (GR-S), neoprene, acrylonitrile-butadiene (Buna-N), silicone	Phenolic-polyvinyl butyral, phenolic-polyvinyl formal, phenolic-neoprene rubber, phenolic-nitrile rubber, modified epoxy
Most used form	Liquid, powder	Liquid, some dry film	Liquid, but all forms common	Liquid, some film	Liquid, paste, film
Common further classifications	By vehicle (water emulsion is most common but many types are solvent dispersions)	By vehicle (most are solvent dispersions or water emulsions)	By cure requirements (heat and/or pressure most common but some are catalyst types)	By cure requirements (all are common); also by vehicle (most are solvent dispersions or water emulsions)	By cure requirements (usually heat and pressure except some epoxy types); by vehicle (most are solvent dispersions or 100% solids); and by type of adherends or end-service conditions
Bond characteristics	Wide range, but generally low strength; good resistance to heat, chemicals; generally poor moisture resistance	Good to 150°F–200°F; poor creep strength; fair peel strength	Good to 200°F–500°F; good creep strength; fair peel strength	Good to 150°F–400°F; never melt completely; low strength; high flexibility	Balanced combination of properties of other chemical groups depending on formulation; generally higher strength over wider temp range
Major type of use ^b	Household, general purpose, quick set, long shelf life	Unstressed joints; designs with caps, overlaps, stiffeners	Stressed joints at slightly elevated temp	Unstressed joints on lightweight materials; joints in flexure	Where highest and strictest end-service conditions must be met; sometimes regardless of cost, as military uses
Materials most commonly bonded	Wood (furniture), paper, cork, liners, packaging (food), textiles, some metals and plastics; industrial uses giving way to other groups	Formulation range covers all materials, but with emphasis on nonmetallics—including wood, leather, cork, and paper.	Epoxy-phenolics for structural uses of most materials; others mainly for wood; alkyds for laminations; most epoxies are modified (alloys)	Few used “straight” for rubber, fabric, foil, paper, leather, plastics, films; also as tapes; most modified with synthetic resins	Metals, ceramics, glass, thermosetting plastics; nature of adherends often not as vital as design or end-service conditions (i.e., high strength, temp)

Source: Schwartz, M., *Encyclopedia of Materials, Parts, and Finishes*, 2nd edn., CRC Press, p. 15.

^a “Alloy,” as used here, refers to formulations containing resins from two or more *different* chemical groups. There are also formulations that benefit from compounding two resin types from the same chemical group (e.g., epoxy-phenolic).

^b Although some uses of the “nonalloyed” adhesives absorb a large percentage of the quantity of adhesives sold, the uses are narrow in scope; from the standpoint of diversified applications, by far the most important use of any group is the forming of adhesive alloys.

derived organic polymers. Broadly, these materials can be divided into two types, thermoplastics and thermosets. Thermoplastic adhesives become softer liquid upon heating and are also soluble. Thermoset adhesives cure upon heating and then become solid and insoluble. Those adhesives that cure under ambient conditions by appropriate choice of chemistry are also considered thermosets.

An example of a thermoplastic adhesive is a hot-melt adhesive. A well-known hot-melt adhesive used since the Middle Ages is sealing wax. Modern hot melts are heavily compounded with wax and other materials. Another widely used thermoplastic adhesive is polyvinyl acetate, which is applied from an emulsion.

Hot-Melt Adhesives

Hot-melt adhesives are 100% solid thermoplastics that are applied in a molten state and form a bond after cooling to a solid state. In contrast to other adhesives, which achieve the solid state through evaporation of solvents or chemical cure, hot-melt adhesives achieve a solid state and resultant strength by cooling. In general, hot-melt adhesives are solid at temperatures below 79°C (175°F). Ideally, as the temperatures increased beyond this point, the material rapidly melts to a low-viscosity fluid that can be easily applied. Upon cooling, the adhesive sets rapidly. Because these adhesives are thermoplastics, the melting-resolidification process is repeatable with the addition and removal of the required amount of heat. Typical application temperatures of hot-melt adhesives are 150°C–290°C (300°F–550°F). See Table A.7.

Materials that are primarily used as hot-melt adhesives include ethylene and vinyl acetate copolymers, polyvinyl acetates, polyethylene, amorphous polypropylene, thermoplastic elastomers such as polyurethane, polyether amide, and block copolymers (e.g., styrene–butadiene–styrene, styrene–isoprene–styrene, and styrene–olefin–styrene), polyamides, and polyesters. Hot-melt adhesives can also be divided into nonpressure-sensitive and pressure-sensitive types. Nonpressure-sensitive adhesives include those for direct bonding and heat sealing. Pressure-sensitive hot-melt adhesives are tacky to the touch and can be bonded by the application of pressure alone at room temperature.

Hot-melt adhesives are used to bond all types of substrates, including metals, glass, ceramics, rubbers, and wood. Primary areas of application include packaging, bookbinding, assembly bonding (such as air filters and footwear), and industrial bonding (such as carpet tape and backings).

Thermoplastic Adhesives

They can be softened or melted by heating and hardened by cooling. They are based on thermoplastic resins (including asphalt oleoresin adhesives) dissolved in solvent or emulsified in water. Most of them become brittle at subzero temperatures and may not be used under stress at temperatures much above 150°F. As they are relatively soft materials, thermoplastic adhesives have poor creep strength. Although lower in strength than all but natural adhesive and suitable only for noncritical service, they are also lower in costs than most adhesives. They are also odorless and tasteless and can be made fungus resistant.

TABLE A.7
Typical Properties of Hot-Melt Adhesives

Property	Ethyl Vinyl Acetate/ Polyolefin Homopolymers and Copolymers	Polyvinyl Acetate	Polyurethane	Polyamides	Polyamide Copolymer	Aromatic Polyamide
Brookfield viscosity (Pa·s)	1–30	1.6–10	2	0.5–7.5	11	2.2
Viscosity test temperature, °C (°F)	204 (400)	121 (250)	104 (220)	204 (400)	230 (446)	204 (400)

Applications	Bookbinding, packaging, toys, automotive, furniture, electronics	Tray forming, packaging, binding, sealing cases and cartons, bottle labels, cans, jars	Laminates	Packaging, electronics, furniture, footwear	Packaging, electronics, binding	Electronics, packaging, binding

^a Relative to other hot-melt adhesives.

A

Pressure Sensitivity

Pressure-sensitive adhesives (PSAs) are mostly thermoplastic in nature and exhibit an important property known as tack. That is, PSAs exhibit a measurable adhesive strength with only a mildly applied pressure. PSAs are derived from elastomeric materials, such as polybutadiene or polyisoprene.

PSAs are capable of holding substrates together when they are brought into contact under brief pressure at room temperature. PSAs are either unsupported or are supported by various carriers, including paper, cellophane, plastic films, cloth, and metal foil. Both single- and double-sided tapes and films are included. Most of the adhesives are based on rubbers compounded with additives, including tackifiers. PSA materials include, in order of decreasing volume and increasing price, natural rubber, styrene-butadiene rubber, reclaimed rubber, butyl rubber, butadiene-acrylonitrile rubber, thermoplastic elastomers, polyacrylates, polyvinyl alkyl ethers, and silicones.

Materials used as PSAs are usually available as solvent systems or hot melts. Substrates are coated with one of these two types of adhesives, and usually no cure of the material is involved upon its application. Adhesive-coated substrates, in their dry state, are permanently tacky at room temperature and do not require activation by water, solvents, or heat. There are two major classes of PSAs: adhesives that are compounded to form PSAs and adhesives that are inherently pressure sensitive and require little or no compounding. Included in the former category are elastomers, and in the latter category are polyacrylates and polyvinyl alkyl ethers.

Tapes, the largest area of application of PSAs, can be classified by construction, function, application, or texture. The construction category includes fabric tapes, paper tapes, foil tapes, film tapes, nonwoven fabric tapes, reinforced tapes, foam tapes, two-faced tapes, and transfer tapes. The backing, rather than the adhesive, is a distinguishing feature of this tape classification. The function category includes masking, holding, ceiling, reinforcing, protecting, bundling, stenciling, splicing, identifying, insulating, packaging, and mounting. The application category includes hospital and first aid tapes, office and graphic art tapes, building industry tapes, packaging and surface protection tapes, electrical tapes, automotive industry tapes, shoe industry tapes, and corrosion protection tapes. The texture category includes floor tiles, wall coverings, automobile wood-grained films, and decorative sheets.

Labels are the second largest application for PSAs. Specific characteristics that are important, and which differentiate labels from tapes, include backing material printability, flatness, ease of die cutting, and release paper properties. The adhesive is applied to the release paper and allowed to dry. These materials are laminated to the label stock.

Thermosetting Adhesives

Based on thermosetting resins, they soften with heat only long enough for the cure to initiate. Once cured, they become relatively infusible up to their decomposition temperature. Although most such adhesives do not decompose at temperatures below 500°F, some are useful only to about 150°F. Different chemical types have different curing requirements. Some are supplied as two-part adhesives and mixed for use at room temperature; some require heat or pressure to bond.

As a group, these adhesives provide stronger bonds than natural, thermoplastic, or elastomeric adhesives. Creep strength is good and peel strength is fair. Generally, bonds are brittle and have little resilience and low impact strength.

Elastomeric Adhesives

Based on natural and synthetic rubbers, elastomeric adhesives are available as solvent dispersions, latexes, or water dispersions. They are primarily used as compounds that have been modified with resins to form some of the adhesive *alloys* discussed in the succeeding text. They are similar to thermoplastics in that they soften with heat but never melt completely. They generally provide high flexibility and low strength and, without resin modifiers, are used to bond paper and similar materials.

Alloy Adhesives

This term refers to adhesives compounded from resins of two or more different chemical families, for example, thermosetting and thermoplastic, or thermosetting and elastomeric. In such adhesives, the performance benefits of two or more types of resins can be combined. For example, thermosetting resins are plasticized by a second resin, resulting in improved toughness, flexibility, and impact resistance.

Structural Adhesives

Structural adhesives are, in general, of the alloy or thermosetting type and have the property of fastening adherends that are structural materials (such as metals and wood) for long periods of time even when the adhesive joint is under load. Phenolic-based structural adhesives were among the first structural adhesives to be developed and used.

Structural adhesives constitute about 35% of the total estimated sales of all adhesives and sealants. Their primary areas of application include automotive, aerospace, appliances, biomedical/dental construction, consumer electronics, fabric, furniture, industrial machines, and marine and sports equipment.

The most common type of structural adhesive is classified as a chemically reactive adhesive. The most widely used materials included in this classification are of epoxies, polyurethanes, modified acrylics, cyanoacrylates, and anaerobics. Chemically reactive adhesives can be subdivided into two groups: one-component systems, which include moisture cure and heat-activated cure categories, and two-component systems, which are subdivided into mix-in and no-mix systems. One-component formulations that cure by moisture from the surrounding air or by adsorbed moisture from the surface of a substrate include polyurethanes, cyanoacrylates, and silicones. A one-component heat-activated system usually consists of two components that are premixed. Chemical families in this group include epoxies and epoxy-nylons, polyurethanes, polyimides, polybenzimidazoles, and phenolics.

The most widely used structural adhesives are based on epoxy resins. Epoxy resin structural adhesives will cure at ambient or elevated temperatures, depending on the type of curative. Urethanes, generated by isocyanate-diol reactions, are also used as structural adhesives. Acrylic monomers have also been utilized as structural adhesives. These acrylic adhesives used an ambient-temperature surface-activated free radical cure. A special type of acrylic adhesive, based on cyanoacrylates (so-called superglue), is a structural adhesive that utilizes an anionic polymerization for its cure. Acrylic adhesives are known for their high strength and extremely rapid cure. Structural adhesives with resistance to high temperatures (in excess of 390°F, or 200°C) for long times can be generated from latter monomers such as polyimides and polyphenol quinoxalines.

Three of the most commonly used adhesives are the modified epoxies, neoprene-phenolics, in final formal phenolics. Modified epoxy adhesives are thermosetting and may be of either the

room-temperature-curing type, which cure by addition of a chemical activator, or the heat-curing type. They have high strength and resist temperature up to nearly 500°F (260°C).

The primary advantage of the epoxies is that they are 100% solids, and there is no problem of solvent evaporation after joining impervious surfaces. Other advantages include high shear strengths, rigidity, excellent self-filleting characteristics, and excellent wetting of metal and glass surfaces. Disadvantages include low peel strength, lack of flexibility, and inability to withstand high impact.

Neoprene-phenolic adhesives are alloys characterized by excellent peel strength but lower shear strength than modified epoxies. They are moderately priced, offer good flexibility and vibration absorption, and have good adhesion to most metals and plastics.

Neoprene-phenolics are solvent types, but special two-part chemically curing types are sometimes used to obtain specific properties.

Vinyl formal-phenolic adhesives are alloys whose properties fall between those of modified epoxies and the thermoset-elastomer types. Vinyl formal-phenolics have good shear, peel, fatigue, and creep strengths and good resistance to heat, although they soften somewhat at elevated temperatures.

They are supplied as solvent dispersions in solution or in film form. In the film form, the adhesive is coated on both sides of a reinforcing fabric. Sometimes, it is prepared by mixing a liquid phenolic resin with vinyl formal powder just prior to use.

Other Adhesives/Cements

Paste adhesives are usually water solutions of starches or dextrans, sometimes mixed with gums, resins, or glue to add strength, and containing antioxidants. They are the cheapest of the adhesives but deteriorate on exposure unless made with chemically altered starches. They are widely employed for the adhesion of paper and paperboard. Much of the so-called vegetable glue is tapioca paste. It is used for the cheaper plywoods, postage stamps, envelopes, and labeling. It has a quick tack and is valued for pastes for automatic box-making machines. Latex paste of the rub-off type is used for such purposes as photographic mounting as they do not shrink the paper as do the starch pastes. Glues are usually water solutions of animal gelatin, and the only difference between animal glues and edible gelatin is in the degree of purity. Hide and bone glues are marketed as dry flake, but fish glue is liquid. Mucilages are light vegetable glues, generally from water-soluble gums.

Rubber cements for paper bonding are simple solutions of rubber in a chemical solvent. They are like the latex pastes in that the excess can be rubbed off the paper. Stronger rubber cements are usually compounded with resins, gums, or synthetics. An infinite variety of these cements is possible, and they are all waterproof with good initial bond, but they are subject to deterioration on exposure, as a rubber is uncured. This type of cement is also made from synthetic rubbers that are self-curing. Curing cements are rubber compounds to be cured by heat and pressure or by chemical curing agents. When cured, they are stronger, give better adhesion to metal surfaces, and have longer life. Latex cements are solvent solutions of rubber latex. They provide excellent tack and give strong bonds to paper, leather, and fabric, but they are subject to rapid disintegration unless cured.

In general, natural rubber has the highest cohesive strength of the rubbers, with rapid initial tack and high bond strength. It also is odorless. Neoprene has the highest cohesive strength of the synthetic rubbers, but it requires tackifiers. Graphite-sulfur rubber (styrene-butadiene) is high-end specific adhesion for quick bonding but has low strength. Reclaimed rubber may be used in cements, but it has low initial tack and needs tackifiers.

Poxylin cements may be merely solutions of nitrocellulose and chemical solvents, or they may be compounded with resins or

plasticized with gums or synthetics. They dry by the evaporation of the solvent and have little initial tack, but because of their ability to adhere to almost any type of surface, they are called household cements. Cellulose acetate may also be used. These cements are used for bonding the soles of women's shoes. The bonding strength is about 10 lb/in.² (0.07 MPa) or equivalent to the adhesive strength of the outer fibers of the leather to be bonded. For hot-press lamination of wood, the plastic cement is sometimes marketed in the form of thin sheet.

Polyvinyl acetate-crotonic acid copolymer resin is used as a hot-dip adhesive for book and magazine binding. It is soluble in alkali solutions, and thus the trim is reusable. Polyvinyl alcohol, with fillers of clay and starch, is used for paperboard containers. Vinyl emulsions are much used as adhesives for laminates.

Epoxy resin cements give good adhesion to almost any material and are heat resistant to about 400°F (204°C). An epoxy resin will give a steel-to-steel bond of 3100 lb/in.² (22 MPa) and aluminum-to-aluminum bond to 3800 lb/in.² (26 MPa).

Some pressure-sensitive adhesives are mixtures of a phenolic resin and a nitrile rubber in a solvent, but adhesive tapes are made with a wide variety of rubber or resin compounds.

Furan cements, usually made with furfural alcohol resins, are strong and highly resistant to chemicals. They are valued for bonding acid-resistant brick and tile.

Acrylic adhesives are solutions of rubber-based polymers in methacrylate monomers. They are two-component systems and have characteristics similar to those of epoxy and urethane adhesives. They bond rapidly at room temperature, and adhesion is not greatly affected by oily or poorly prepared surfaces. Other advantages are low shrinkage during cure, high peel and shear strength, excellent impact resistance, and good elevated temperature properties. They can be used to bond a great variety of materials, such as wood, glass, aluminum, brass, copper, steel, most plastics, and dissimilar metals.

Ultraviolet cure adhesives are anaerobic structural adhesives formulated specifically for glass-bonding applications. The adhesive remains liquid after application until ultraviolet light triggers the curing mechanism.

A ceramic adhesive developed by the Air Force for bonding stainless steel to resist to 1500°F (816°C) is made with a porcelain enamel frit, iron oxide, and stainless steel powder. It is applied to both parts and fired at 1750°F (954°C), giving a shear strength of 1500 lb/in.² (10 MPa) in the bond. But ceramic cements that require firing are generally classed with ordinary adhesives. Wash-away adhesives are used for holding lenses, electronic crystal wafers, or other small parts for grinding and polishing operations. They are based on acrylic or other low-melting thermoplastic resins. They can be removed with a solvent or by heating.

Electrically conductive adhesives are made by adding metallic fillers, such as gold, silver, nickel, copper, or carbon powder. Most conductive adhesives are epoxy-based systems, because of their excellent adhesion to metallic and nonmetallic surfaces. Silicones and polyimides are also frequently the base in adhesives used in bonding conductive gaskets to housings for electromagnetic and radio frequency interference applications.

Properties

An important property for a structural adhesive is resistance to fracture (toughness). Thermoplastics, because they are not cured, can deform under load and exhibit resistance to fracture. As a class, thermosets are quite brittle, and thermoset adhesives are modified by elastomers to increase their resistance to fracture. See Table A.8.

TABLE A.8
Properties of Diallyl Phthalate Molding Compounds

ASTM Test		Property	Filler			
			Polyester	Long Glass	Short Glass	Arc-Track Resistant

Applications

Hot-melt adhesives are used for the manufacture of corrugated paper, in packaging, in carpeting, in bookbinding, and in shoe manufacture. Pressure-sensitive adhesives are most widely used in the form of coatings on tapes. These pressure-sensitive adhesive tapes have numerous applications, from electrical tape to surgical tape. Structural adhesives are applied in the form of liquids, pastes, or 100% adhesive films. Epoxy liquids and pastes are very widely used adhesive materials, having application in many assembly operations ranging from general industrial to automotive to aerospace vehicle construction. Solid-film structural adhesives are used widely in aircraft construction. Acrylic adhesives are used in thread-locking operations and in small-assembly operations such as electronics manufacture, which require rapid cure times. The largest-volume use of adhesives is in plywood and other timber products manufacture. Adhesives for wood bonding range from the natural products (such as blood or casein) to the very durable phenolic-based adhesives.

Trends and Advantages of Adhesives

Design engineers have many reasons to replace mechanical fasteners with adhesives, including

- Higher energy costs pushing weight reduction in fuel efficiency
- Manufacturers wanting to reduce costs, reduce the number of components in an assembly, and improve productivity

- Manufacturers looking to improve product quality by eliminating process variables
- Design engineers working with dissimilar materials such as plastics, composites, and new metal alloys
- Components becoming smaller and lighter with less space in the design for mechanical fasteners and less space on the manufacturing floor for mechanical fastening processes
- Manufacturers automating or processes, with structural adhesives more adaptable to automated processes

Structural adhesives are generally defined as “load-bearing” adhesives. Depending on the application, they can withstand heavy loads to 4000 psi or even higher. Regardless of the application, a structural adhesive won’t fail when a bonded joint is stressed to its yield point. Structural adhesives are part of the structure of their assemblies; they are designed to meet the performance specifications of the entire assembly.

Structural adhesives can include acrylics, epoxies, and urethanes. Acrylics are formulated to provide good adhesion with metal, composites, and thermoplastics. In general, they are fast setting and curing and offer significant product gains. Epoxies provide excellent adhesion to metals and rigid substrates that include thermoset plastics and composites. Epoxies are known for durability, chemical and temperature resistance, and low shrinkage. Urethanes and polyurethanes are suitable for use with thermoplastics; because of their flexibility, they work well with softer, less rigid materials.

Using structural adhesives instead of mechanical fasteners lets you assemble dissimilar materials with higher weight loads and distribute stress evenly across the bond. Structural adhesives won't negatively affect the integrity and strength of the materials—there are no holes, rivets, or other mechanical fasteners to weaken the structure of the joined materials. Structural adhesive also results in a more aesthetically pleasing design, an important criteria in many industries, including automotive, medical equipment, and appliance. In addition, structural adhesives can fill large gaps between substrates and seal joints against corrosion and environmental extremes. They are also easily integrated into automated manufacturing processes, letting you explore new designs and maximize the use of the materials.

In one application, a trade-show display manufacturer was looking for a lightweight, durable solution to bond aluminum hinges to polypropylene panels. The bonds needed to stand up to extreme shipping and handling conditions and heavy use. It was suggested and tested structural adhesives that offered advantages and bond strength and allowed for joining of dissimilar materials—requirements that traditional mechanical joining methods are not able to accommodate.

Perhaps the greatest advantage of structural adhesives is cost. These adhesives are lower in cost than labor-intensive mechanical fastening technologies like rivets, screws, or nuts and bolts.

Of course, structural adhesives are not appropriate for every application. The required time to cure and fixture, application can be messy, they must be properly handled, and they can sometimes be difficult to assemble.

As the use of structural adhesives grows, manufacturing engineers and engineers are looking for help who can best select the best structural adhesives and materials for their applications and manufacturing process. They need to

- Analyze the application for materials and adhesive requirements
- Recommend materials and adhesives and suppliers
- Test the materials and adhesives
- Develop prototypes for customer testing
- Provide design for manufacturability

In addition, the outside help if not available in-house should be able to qualify materials and adhesives based on the following in-house laboratory testing:

- Temperature resistance
- Performance at upper temperature limits
- Shear, tensile, and peel strength
- Outgassing
- Dielectric strength and electrical conductivity
- Thermal conductivity
- Slitting widths and tolerances

For structural pressure-sensitive and other tapes, one must be knowledgeable in precision die cutting using rotary or laser technology, water jet cutting, and dieless cutting. In addition, precision slitting and rewinding, laminating, and printing are also critical capabilities.

Adhesive Assembly

A group of materials or parts, including adhesive, that are placed together for bonding or that have been bonded together. See also *assembly adhesive*.

Adhesive Bond

Attractive forces, generally physical and character, between that adhesive in the base materials. Two principal interactions that contribute to the adhesion are van der Waals bonds and dipole bonds. See also *van der Waals bond*.

Adhesive Bonding

A material-joining process in which an adhesive, placed between the faying surfaces (adherends), solidifies to produce an adhesive bond.

Adhesive Dispersion

A two-phase system in which one phase is suspended in a liquid. Compare with *emulsion*.

Adhesive Failure

Rupture of an adhesive bond such that the separation appears to be at the adhesive–adherend interface. Sometimes termed failure in adhesion. Compare with *cohesive failure*.

Adhesive Film

A synthetic resin adhesive, with or without a film carrier fabric, usually of the thermosetting type, in the form of a thin film of resin, used under heat and pressure as an interleaf in the production of bonded structures.

Adhesive Joint

Location at which two adherends are held together with a layer of adhesive. See also *bond*.

Adhesive Strength

The strength of the bond between an adhesive and an adherend.

Adhesive System

An integrated engineering process that analyzes the total environment of a potential bonded assembly to select the most suitable adhesive, application method, and dispensing equipment.

Adhesive Wear

(1) Wear by transference of material from one surface to another during relative motion due to a process of solid-phase welding. Particles that are removed from one surface are either permanently or temporarily attached to the other surface. (2) Wear due to localized bonding between contacting solid surfaces leading to material transfer between the two surfaces or loss from either surface. (3) Removal of material from a metal surface by a repeated welding and tearing action. When two surfaces move relative to each other in unlubricated contact, the high points on the two surfaces can weld together as a result of local high temperatures and disruption of surface films. Continuing movement immediately breaks the weld but the resultant surface damage becomes a site for further welding and tearing cycles. As the damage increases, it may be referred to, progressively, as scuffing, galling, and finally, seizure. The damage may also be described as pitting, scoring, or gouging, but these terms are also used for damage by other mechanisms. Compare with *abrasive wear*.

A

Adhesive, Cold-Setting

See *cold-setting adhesive*.

Adhesive, Contact

See *contact adhesive*.

Adhesive, Gap-Filling

See *gap-filling adhesive*.

Adhesive, Heat-Activated

See *heat-activated adhesive*.

Adhesive, Heat-Sealing

See *heat-sealing adhesive*.

Adhesive, Hot-Melt

See *hot-melt adhesive*.

Adhesive, Hot-Setting

See *hot-setting adhesive*.

Adhesive, Intermediate-Temperature-Setting

See *intermediate-temperature-setting adhesive*.

Adhesive, Pressure-Sensitive

See *pressure-sensitive adhesive*.

Adhesive, Structural

See *structural adhesive*.

Adiabatic

Occurring with no addition or loss of heat from the system under consideration.

Adjustable Bed

Bed of a press designed so that the die space height can be varied conveniently.

Admiralty Metal

There are copper alloys noted for good resistance in low-velocity freshwater and seawater and thus are used for condenser, distiller, and heat-exchanger tubing and related equipment in these environments. Also known as inhibited admiralty metal and admiralty brass, they comprise nominally 71.5% copper, 28% zinc, plus small amounts of lead (0.07 maximum) and iron (0.06 maximum) and either 0.02–0.06 arsenic (arsenical admiralty metal), 0.02–0.10 antimony (antimonial admiralty metal), or 0.02–0.10 phosphorous (phosphorized admiralty metal). Admiralty brass, an alloy of 70% copper,

29% zinc, and 1% tin, has good corrosion resistance particularly in seawater, hence its use for condenser tubing on steam-driven vessels. Admiralty gunmetal, an alloy of 88% copper, 10% tin, and 2% zinc, has good strength, corrosion resistance and good casting characteristics, and historically used for naval guns. Though admiralty metal is available in the annealed and cold-work tempers, the annealed condition is often preferred because of the alloy's susceptibility to stress corrosion. Typical tensile properties in the annealed condition are 45,000–53,000 lb/in.² (310–365 MPa) ultimate strength, 13,002–22,000 lb/in.² (89–152 MPa) yield strength, and 65%–70% elongation. Cold working appreciably increases strength.

Admixture

(1) The addition and homogeneous dispersion of discrete components, before cure of a polymer. (2) A material other than water, aggregates, hydraulic cement, and fiber reinforcement used as an ingredient of concrete or mortar and added to the batch immediately before or during its mixing. (3) Material added to (cement) mortars as a water-repellent or coloring agent or to retard or hasten setting.

Adsorbent

A material used to remove odor, taste, haze, and color from oils, foods, pharmaceuticals, or chemicals by selected adsorption of the impurities. Such materials are also called adsorbates. The common adsorbates are activated carbon, or activated clays, alumina, magnesium silicate, or silica gel. The noncarbonaceous adsorbents are used for decolorizing vegetable, animal, or mineral oils, but activated carbon may also be used in conjunction with clays to adsorb color bodies not removed by the clay.

Absorbents called molecular sieves are used to separate chemicals of different molecular diameters without regard to their boiling points. The adsorbents used in vacuum tubes to adsorb or combine with residual gases are called getters. Bulk getters are sheets or wires of zirconium, tantalum, or columbium mounted on the hot electrode to trap gases at temperatures of 900°F–2200°F (482°C–1204°C). Thorium or thorium–misch metal may be used as getters for high temperatures by a coating sintered on the tube anode.

Adsorption

The adhesion of the molecules of gases, dissolved substances, or liquids in more or less concentrated form, to the surfaces of solids or liquids with which they are in contact. The concentration of a substance at a surface or interface of another substance forming a fairly loosely bonded molecular layer.

Adsorption Chromatography

Chromatography based on differing degrees of adsorption of sample compounds onto a polar stationary phase. See also *liquid–solid chromatography*.

Advanced Ceramics

Ceramic materials that exhibit superior mechanical properties, corrosion/oxidation resistance, or electrical, optical, and/or magnetic properties. This term includes many monolithic ceramics as well as particulate-, whisker-, and fiber-reinforced glass, glass-ceramics, and ceramic-matrix composites. Also known as engineering, fine, or technical ceramics. In contrast with *traditional ceramics*.

Advanced Composites

Composite materials that are reinforced with continuous fibers having a modulus higher than that of fiberglass fibers. The term includes metal-matrix and ceramic-matrix composites, as well as carbon-carbon composites.

Ae_{cm} , Ae_1 , Ae_3 , Ae_4

Defined under *transformation temperature*.

Aerate

To fluff up molding sand to reduce its density.

Aerated Bath Nitriding

A type of liquid nitriding in which air is pumped through the molten bath creating agitation and increased chemical activity.

Aeration

(1) Exposing to the action of air. (2) Causing air to bubble through. (3) Introducing air into a solution by spraying, stirring, or a similar method. (4) Supplying or infusing with air, as in sand or soil.

Aeration Cell (Oxygen Cell)

See *differential aeration cell*.

Aerodynamic Lubrication

See *gas lubrication*.

Aerogel

A highly porous, sometimes more than 98%, extremely lightweight, and nearly transparent solid formed from a gel by replacing the liquid with a gas with little change in volume. The fine, airy cell structure can support more than 1000 times its weight and is considered a superior thermal and perhaps acoustic insulator. Silica, the most common aerogel, is typically made by dissolving silicon alkoxides in a solution, curing it to form a gel, and drying the gel with carbon dioxide at about 1150 lb/in.² (7.9 MPa) and a high temperature.

AFS 50-70 Test Sand

A rounded quartz sand specified for use as an abrasive in the dry sand-rubber wheel abrasive wear test (ASTM G 65).

Aerosol

A dispersion of particles in air, particularly the chemical dispensing of a liquid or a finely divided powder substance by a gas propellant under pressure. The common aerosol can system was developed during World War II for dispensing insecticides. Substances commonly dispensed by the aerosol process include resins, paints, waxes, and cosmetics. Chlorofluorocarbons, hydrocarbons, and carbon dioxide have been used as propellants. The main propellants now are liquefied hydrocarbons, carbon dioxide, and nitrogen. Aerothene MM, of Dow Chemical Company, is a methylene chloride that has properties

needed for the efficient functioning of carbon dioxide and hydrocarbon propellants in cosmetic aerosol applications. In noncosmetic aerosol applications, such as paints and insecticides, hydrocarbons claimed 45% of the market. The principal objection to their use for cosmetic aerosols has been their flammability.

Aerostatic Lubrication

See *pressurized gas lubrication*.

Afterbake

See *post cure*.

Afterblow

In the basic Bessemer steelmaking process, the main flow produces a strong flame resulting from the carbon removal. Continuation of the blow after carbon removal, termed the afterblow, produces a lesser flame associated with phosphorus removal.

Agate

A natural mixture of crystalline and colloidal silica, but consisting mainly of the mineral chalcedony. It usually occurs in irregular banded layers of various colors derived from mineral salts, and when polished, it has a waxy luster. Agate is used for knife edges and bearings of instruments, for pestles and mortars, for textile rollers, and for ornamental articles, and the finer specimens are employed as gemstones.

Age

Any process taking place over a period of time. Examples include an increase in hardness, as in strain age hardening, or an increase in the hysteresis losses in magnetic steels and the term is a common contraction of age harden.

Age Hardening

Hardening by *aging* (heat treatment) usually after rapid cooling or cold working.

An increase in hardness occurring spontaneously over a period of time, particularly that observed in alloys that have been solution treated. See *precipitation hardening* and *strain age hardening*.

Age Hardening (of Grease)

The increasing consistency of a lubricating grease with time of storage.

Age Softening

Spontaneous decrease of strength and hardness that takes place at room temperature in certain strain hardened alloys, especially those of aluminum.

Agglomerate

This clustering together of a few or many particles, whiskers, or fibers, or a combination thereof, into a larger solid mass.

A

Aggregate

(1) A dense mass of particles held together by strong intermolecular or atomic cohesive forces. (2) Granular material, such as sand, gravel, crushed stone, or iron blast-furnace slag, used with a cementing medium to form hydraulic-cement concrete or mortar. (3) A hard, coarse material usually of mineral origin used with an epoxy binder (or other resin) in plastic tools. Also used in flooring or as a surface medium.

Aggressive Tack

Synonym for *dry tack*.

Aging

(1) The effect on materials of exposure to an environment for a prolonged interval of time. (2) The process of exposing materials to an environment for a prolonged interval of time in order to predict in-service lifetime. (3) Generally, the degradation of properties or function with time.

Aging (Heat Treatment)

A change in the properties of certain metals and alloys that occurs at ambient or moderately elevated temperatures after hot working or a heat treatment (quench aging in ferrous alloys, natural or artificial aging in ferrous and nonferrous alloys) or after a cold working operation (strain aging). The change in properties is often, but not always, due to a phase change (precipitation) but never involves a change in chemical composition of the metal or alloy. See also *age hardening*, *artificial aging*, *interrupted aging*, *natural aging*, *overaging*, *precipitation hardening*, *precipitation heat treatment*, *progressive aging*, *quench aging*, *step aging*, and *strain aging*.

Agitator

A device to intensify mixing. Example is a high-speed stirrer or paddle in a blender or drum of a mill.

Agricultural Steel

A largely obsolete term implying plain carbon steels as used for simple farming implements such as plows, spades possibly with a hard face deposit.

Air

The gas atmosphere in which we live. It comprises about 80% nitrogen, 20% oxygen, small quantities of carbon dioxide, rare gases such as argon, and pollutants such as sulfur dioxide.

Air Acetylene Welding

A fuel gas welding process in which coalescence is produced by heating with a gas flame or flames obtained from the combustion of acetylene with air, without the application of pressure, and with or without the use of filler metal.

Air Arc Cutting

Cutting processes in which the material to be cut is melted by an electric arc struck between an electrode and the workpiece and the molten materials ejected by a high-velocity air jet. Terms such as air carbon arc cutting and air metal arc cutting indicate the material of the electrode.

Air Bearing

A bearing for a shaft or sliding interface where air is induced to keep the faces separate and act as a lubricant.

Air Bend Die

Angle forming dies in which the metal is formed without striking the bottom of the die. Metal contact is made at only three points in the cross section; the nose of the male die and the two edges of a V-shape die opening.

Air Bending

Bending in an *air bend die*.

Air Blasting

See *blasting* or *blast cleaning*.

Air Cap (Thermal Spraying)

A device for forming, shaping, and directing an air pattern for the atomization of wire or ceramic rod.

Air Carbon Arc Cutting (AAC)

An arc cutting process in which metals to be cut are melted by the heat of a carbon arc, and the molten metal is removed by a blast of air.

Air Channel

A groove or hole that carries the vent from a core to the outside of a mold.

Air Circulation Furnace

An air furnace that has some system to circulate air to ensure even heating of the contents.

Air Classification

The separation of metal powder into particle-size fractions by means of an air stream of controlled velocity and application of the principle of *elutriation*.

Air Dried

Refers to the air drying of a casting core or mold without the application of heat.

Air Dried Strength

Strength (compressive, shear, or tensile) of the refractory (sand) mixture after being air dried at room temperature.

Air Feed

A *thermal spraying process* variation in which an air stream carries the powdered material to be sprayed through the gun in and to the heat source.

Air Furnace

Reverberatory-type furnace in which metal is melted by heat from fuel burning at one end of the hearth, passing over the bath toward the stack at the other end. It is also reflected from the roof and side walls. The atmosphere is untreated air as opposed to fuel combustion products, some gas deliberately introduced, or a vacuum. See also *reverberatory furnace*.

Air Gap

In extrusion coating, the distance from the die opening to the nip formed by the pressure roll and the chill roll.

Air Gap (in Welding)

The distance between the electrode and the workpiece over which an electric arc is struck.

Air Gap (in an Electromagnetic Context)

A gap crossed by the magnetic flux to complete the magnetic circuit. In a generator, it is the radial gap between rotor and stator, and even when the machine is hydrogen cooled and the gap is filled with hydrogen, it is still referred to as the air gap.

Air Hammer

In lubrication, a type of instability, basically a resonance, that occurs in externally pressured gas bearings.

Air Hole

A hole in a casting caused by air or gas trapped in the metal drawing solidification.

Air Setting

The characteristic of some materials, such as refractory cements, core pastes, binders, and plastics, to take permanent set at normal air temperatures.

Air Vent

A small outlet to prevent entrapment of gases in a molding or tooling fixture.

Air-Assist Forming

A method of thermoforming in which air flow or air pressure is employed to preform plastic sheet partially just before the final pull-down onto the mold using vacuum.

Air-Bubble Void

Air entrapment within a molded item or between the plies of reinforcement or within a bond line or encapsulated area; localized, noninterconnected, and spherical in shape.

Air-Hardening Steel

A steel containing sufficient carbon and other alloying elements to harden fully during cooling in air or other gaseous media from a temperature above its transformation range. The term should be restricted to steels that are capable of being hardened by cooling in air in fairly large sections, about 2 in. (50 mm) or more in diameter. Same as self-hardening steel.

Air-Lift Hammer

A type of gravity-drop hammer in which the ram is raised for each stroke by an air cylinder. Because length of stroke can be controlled, ram velocity and therefore the energy delivered to the workpiece can be varied. See also *drop hammer* and *gravity hammer*.

Air-Slip Forming

A variation of vacuum snap-back *thermoforming* in which the male mold is enclosed in a box such that when the mold moves forward toward the hot plastic, air is trapped between the mold in the plastic sheet. As the mold advances, the plastic is kept away from it by this air cushion until the full travel of the mold is completed, at which point, a vacuum is applied, destroying the cushion and forming the part against the plug.

Alabaster

The naturally occurring crystalline form of gypsum.

Albumin

The water-soluble and alcohol-soluble protein obtained from blood, eggs, or milk and used in adhesives, textile and paper finishes, leather coatings, varnishes, as a clarifying agent for tannins, and in oil emulsions. Crude blood albumin is a brown amorphous lumpy material obtained by clotting slaughterhouse blood and dissolving out the albumin. The remaining dark-red material is made into ground blood and marketed as a fertilizer. Blood albumin is sold as clear, pale, amber, and colored powders. Blood albumin from human blood is a stable, dry, white powder. It is used in water solution for treatment of shock.

The material of egg white is sometimes spelled albumen. Egg white is a complex mixture of at least eight proteins, with sugar and inorganic salts. More than half of the total is the protein oval albumin, a strong coagulating agent, and another large percentage consists of conalbumin, which forms metal complexes and unites with iron in the human system. Two of the proteins not so desirable in the human body are ovomucoid, which inhibits the action of the digestive enzyme trypsin, and avidin, which combines with and destroys

A

the action of the growth vitamin biotin. Egg albumin is prepared from the dried egg white and is marketed in yellowish amorphous lumps or powdered.

Alclad

Composite wrought product comprised of an aluminum alloy core having one or both surfaces a metallurgically bonded aluminum or aluminum alloy coating that is anodic to the core and thus electrochemically protects the core against corrosion.

Alcohol

The common name for ethyl alcohol, but the term properly applies to a large group of organic compounds that have important uses in industry, especially in solvents and in the preparation of other materials. A characteristic of all alcohols is the monovalent $-OH$ group. In the primary alcohols, there is always a $\cdot CH_2OH$ group in the molecule. The secondary alcohols have a $\cdot CHOH$ group, and the tertiary alcohols have a distinctive $\cdot COH$ group. Alcohols with one OH group are called monohydroxy alcohols or polyhydric alcohols. Another method of classification is by the terms "saturated" and "unsaturated." The common alcohols used in industry are ethyl, methyl, amyl, butyl, isopropyl, and octyl. The alcohols vary in consistency. Methyl alcohol is like water, amyl alcohol is oily, and melissyl alcohol is a solid. Many of the alcohols are most easily made by fermentation; others are produced from natural gas or from petroleum hydrocarbons. Much of the production of ethyl alcohol is from blackstrap molasses. Alcohols, generally colorless, are similar to water in some ways and are neither alkaline nor acid in reaction.

Methyl alcohol, commonly known as wood alcohol, has the chemical name methanol. It is also referred to as carbinol. A colorless, poisonous liquid of composition CH_3OH , it was originally made by the distillation of hardwoods. It is now produced chiefly by catalytic reduction of carbon monoxide and dioxide by hydrogen.

Fuel use, either directly or for making methyl tert-butyl ether (MTBE), is growing. MTBE makes up as much as 15% of reformulated gasoline. Methanol is used as a solvent in lacquers, varnishes, and shellac. On oxidation, it yields formaldehyde, and it is used in making the latter product for synthetic molding materials.

Solidified alcohol, marketed in tins and used as a fuel in small stoves, is a jellylike solution of nitrocellulose in methyl alcohol. It burns with a hot flame. Sterno is this material, while Trioxane, employed for the same purpose, is an anhydrous formaldehyde trimer but has the disadvantage of being water soluble.

Butyl alcohol is a colorless liquid used as a solvent for paints and for varnishes and in the manufacture of dyes, plastics, and many chemicals. There are four forms of this alcohol, with the normal or primary butyl alcohol being the most important. Normal butyl alcohol, $CH_3(CH_2)_2\cdot OH$, in this form, known as butanol, has strong solvent power and is valued where a low evaporation rate is desired, such as in latexes and nitrocellulose lacquer.

Fluoroalcohols are alcohols in which fluorine is substituted for hydrogen in the nonalcohol branch. They have the general composition $H(CF_2CF_2)_2CH_2OH$, and as solvents, they dissolve some synthetic resins that resist common solvents. Some of the esters are used as lubricants for temperatures to $500^\circ F$ ($260^\circ C$). Acetylenic alcohols are methyl butanol and used as a solvent, in metal pickling, in plating, and in vitamin manufacture, and methyl pentynol. It is a powerful solvent. It has hypnotic qualities and is also used for tranquilizing fish in transport.

Fatty acid alcohols, made from fatty acids synthetically, have the general formula $CH_3(CH_2)_2OH$, ranging from the C_8 of octyl alcohol to the C_{18} of stearyl alcohol. They are easily esterified, oxidized or ethoxylated, and used for making cosmetics, detergents, emulsifiers, and other chemicals. Polyols are polyhydric alcohols containing many hydroxyl, $-OH$, radicals. They react easily with isocyanates to form urethane.

Alcomax

A series of alloys with strong permanent magnet characteristics. Iron based with about 20% cobalt, 15% nickel, 10% aluminum, and small quantities of other elements such as titanium, niobium, and copper. They are hard and brittle and can only be formed by casting or powder metal processes. Alnico alloys are similar.

Aldehydes

A group name for substances made by the dehydrogenation or oxidation of alcohols, such as formaldehyde from methyl alcohol. By further oxidation, the aldehydes formed corresponding acids, as formic acid. The aldehydes have the radical group $-CHO$ in the molecule, and because of their ease of oxidation, they are important reducing agents. They are also used in the manufacture of synthetic resins and many other chemicals. Aldehydes occur in animal tissues and in the odorous parts of plants.

Acetaldehyde is a water-white flammable liquid with an aromatic penetrating odor, used as a reducing agent, preservative, and for silvering mirrors, and in the manufacture of synthetic resins, dye-stuffs, and explosives. Also called ethanal, it has the composition of $CH_3\cdot CHO$ and is made by the direct liquid-phase oxidation of ethylene.

Acrolein is acrylic aldehyde, $CH_2 : CH\cdot CHO$, a colorless volatile liquid whose vapor is irritating to the eyes and nose, and the unpleasant effect of scorching fat is due to the acrolein formed. Acrolein is made by oxidation of propylene with a catalyst. It polymerizes easily and can be copolymerized with ethylene, styrene, epoxies, and other resins to form various types of plastics. Its reactive double bond and carbonyl group make it a useful material for chemical synthesis. It is used as an antimicrobial agent for controlling algae, microbes, mollusks, and aquatic weeds.

Algorithm

A procedure for solving a mathematical problem by a series of operations. In *computed tomography*, the mathematical process used to convert the transmission measurements into a cross-sectional image. Also known as reconstruction algorithm.

Aligning Bearing

A bearing with an external spherical seat surface that provides a compensation for shaft or housing deflection and misalignment. Compare with *self-aligning bearing*.

Alignment

In mechanical or electrical adjustment of the components of an optical device so that the path of the radiating beam coincides with the optical axis or other predetermined path in the system. See also *mechanical alignment* and *voltage alignment*.

Aliphatic Hydrocarbons

Saturated hydrocarbons having an open-chain structure, for example, gasoline and propane.

Aliphatic Polyketones

Semicrystalline thermoplastics developed by Shell Chemicals, which discontinued production in the year 2000. Called Carilon polymers, these polyketones consist of a perfectly alternating linear structure of ethylene and carbon monoxide with a minor amount of propylene for excellent chemical resistance and dimensional stability in harsh environments and good mechanical properties. They are especially resistant to salt solutions, hydrocarbons, oil field chemicals, weak acids and bases, and soaps and detergents, resist hydrolysis, dissolution, and plasticization in a broad range of chemicals; exhibit minimal swelling in harsh hydrocarbon environments; and provide good barrier properties, or permeation resistance, to methane, carbon dioxide, and hydrogen sulfide and has a melting temperature of 428°F (220°C).

Aliquot

A representative sample of a larger quantity.

Alkali

A caustic hydroxide characterized by its ability to neutralize acids and form soluble soaps with fatty acids. Fundamentally, alkalis are inorganic alcohols, with the monovalent hydroxyl group OH in the molecule, but in the alkalis, this group is in combination with a metal or an ammonia group, and alkalis have none of the characteristics of alcohols. All alkalis are basic and have a pH value from 7 to 14. They neutralize acids to form a salt and water. The common alkalis are sodium hydroxide and potassium hydroxide, which are used in making soaps, soluble oils, and cutting compounds, and cleaning solutions, and for etching aluminum. All the alkalis have a brackish taste and a soapy feel; most corrode animal and vegetable tissues.

Alkali Metals

A metal in group IA of the periodic system—namely, lithium sodium, potassium, rubidium, cesium, and francium, as well as calcium, and barium because of the basic reaction of their oxides, hydroxides, and carbonates. Carbonates of these metals are called fixed alkalis. The metals show a gradation in properties and increase in chemical activity with increase in atomic weight.

All are silvery white and very soft. They tarnish rapidly in air and decompose water at ordinary temperatures. In the alkali metals, the electron bonding is so weak that even the impact of light rays knocks electrons free. All have remarkable affinity for oxygen. Rubidium and cesium ignite spontaneously in dry oxygen. Calcium, strontium, and barium are also called earth metals. Thin films of the alkali metals are transparent to ultraviolet light but opaque to visible light.

Alkaline

(1) Having properties of an alkali. (2) Having a pH greater than 7.

Alkaline Cleaner

A material blended from alkali hydroxides in such alkaline salts as borates, carbonates, phosphates, or silicates. The cleaning action

may be enhanced by the addition of surface-active agents and special solvents.

Alkaline Earth Metal

A metal in group IIA of the periodic system—namely, beryllium, magnesium, calcium, strontium, barium, and radium—so-called because the oxides or “earths” of calcium, strontium, and barium were found by the early chemists to be alkaline in reaction.

Alkaline Sodium Picrate

An etchant for steel. Typically, 25 g of sodium hydroxide plus 2 g of picric acid dissolved in 100 cm³ of hot water. When used hot, it will slowly darken cementite.

Alkyd Coatings

They are used for such diverse applications as air-drying water emulsion wall paints and baked enamels for automobiles and appliances. The properties of oil-modified alkyd coatings depend upon the specific oil used as well as the percentage of oil in the composition. In general, they are comparatively low-cost and have excellent color retention, heat resistance, and salt spray resistance. The low-modified alkyds can be further modified with other resins to produce resin-modified alkyds. The resin is sometimes added during manufacture of the alkyd and becomes an integral part of the alkyd, or the modifying resin is blended with the alkyd when the paint is formulated. When mixed with urea formaldehyde or melamine resin, harder and more resistant baked enamels are produced. Alkyds blended with ethyl cellulose are used as tough flexible coatings for electric cable. Other resins blended with alkyds to produce special or improved properties include phenolic, resin, vinyl, and silicone.

Alkyd Plastics

These are molding compounds composed of a polyester resin and usually a diallyl phthalate monomer plus various inorganic fillers, depending on the desired properties. The raw material is produced in three forms—granular, putty, and glass fiber reinforced. As a class, the alkyds have excellent heat resistance up to about 300°F (149°C), high stiffness, and moderate tensile and impact strength. Their low moisture absorption combined with good dielectric strength makes them particularly suitable for electronic and electrical hardware, such as switchgears, insulators, and parts for motor controllers and automotive ignition systems. They are easily molded at low pressures and cure rapidly.

These thermoset plastics are based on resins composed principally of polymeric esters, in which the recurring ester groups are an integral part of the main polymer chain, and in which ester groups occur in most cross-links that may be present between chains.

Alkyd Resins

A group of thermosetting synthetic resins known chemically as hydroxycarboxylic resins, of which the one produced from phthalic anhydride and glycerol is representative. They are made by the esterification of a polybasic acid with a polyhydric alcohol and have the characteristics of homogeneity and solubility that make them especially suitable for coatings and finishes, plastic molding compounds, caulking compounds, adhesives, and plasticizers for other resins. The resins have high adhesion to metals; are transparent, easily

A

colored, tough, flexible, heat and chemical resistant; and have good dielectric strength. They vary greatly with the raw materials used in with varying percentage compositions, from soft rubbery gums to hard, brittle solids. Phthalic anhydride imparts hardness and stability. Maleic acid makes a higher-melting point resin. Azelaic acid gives a softer and less brittle resin. The long-chain dibasic acids, such as adipic acid, give resins of great toughness and flexibility. In place of glycerol, the glycols yield soft resins, and sometimes, the glycerol is modified with a proportion of glycol. The resins are reacted with oils, fatty acids, or other resins, such as urea or melamine, to make them compatible with drying oils and to impart special characteristics.

Since alkyd resins are basically esterification products of innumerable polybasic acids and polyhydric alcohols and can be modified with many types of oils and resins; the actual number of different alkyd resins is unlimited, and the users' specification is normally by service requirements rather than composition.

Alkyds

Alkyds are part of the group of materials that includes bulk-molding compounds and sheet-molding compounds. They are processed by compression, transfer, or injection molding. Faster molding cycles at low pressure make alkyds easier to mold like many other thermosets. They represent the introduction to the thermosetting plastics industry of the concept of low-pressure, high-speed molding.

Alkyds are furnished in granular compounds, extruded ropes or logs, bulk-molding compound, flake, and puttylike sheets. Except for the putty grades, which may be used for encapsulation, these compounds contain fibrous reinforcement. Generally, the fiber reinforcement in rope and logs is longer than that in granular compounds and shorter than that in flake compounds. Thus, strength of these materials is between those of granular and flake compounds. Because fillers which are opaque and the resins are amber, translucent colors are not possible. Opaque, light shades can be produced in most colors, however.

Molded alkyd parts resist weak acids, organic solvents, and hydrocarbons such as alcohol and fatty acids; they are attacked by alkalis.

Depending on the properties desired in the finished compound, the fillers used are clay, asbestos, fibrous glass, or combinations of these materials. The resulting alkyd compounds are characterized in their molding behavior by the following significant features: (1) no liberation of volatiles during the cure, (2) extremely soft flow, and (3) fast cure at molding temperatures.

Although the general characteristics of fast cure at low-pressure requirements are common to all alkyd compounds, they may be divided into three different groups that are easily discernible by the physical form in which they are manufactured.

1. Granular types, which have mineral or modified mineral fillers, providing superior dielectric properties and heat resistance
2. Putty types, which are quite soft and particularly well-suited for low-pressure molding
3. Glass fiber-reinforced types, which have superior mechanical strengths

Granular Types

The physical form of materials in this group is that of a free-flowing powder. Thus, these materials readily lend themselves to conventional

molding practices such as volumetric loading, preforming, and high-speed automatic operations. The outstanding properties of parts molded from this group of compounds are high dielectric strength at elevated temperatures, high arc resistance, excellent dimensional stability, and high heat resistance. Compounds are available within this group that are self-extinguishing and certain recently developed types display exceptional retention of insulating properties under high humidity conditions.

These materials have found extensive use as high-grade electrical insulation, especially in the electronics field. One of the major electronic applications for alkyd compounds is in the construction of vacuum tube bases, where the high dry insulation resistance of the material is particularly useful in keeping the electrical leakage between pins to a minimum. In the television industry, tuner segments are frequently molded from granular alkyd compound since electrical and dimensional stability is necessary to prevent calibration shift in the tuner circuits. Also, the granular alkyds have received considerable usage in automotive ignition systems where retention of good dielectric characteristics at elevated temperatures is vitally important.

Putty Types

This group contains materials that are furnished in soft, puttylike sheets. They are characterized by very low-pressure molding requirements (less than 800 psi) and are used in molding around delicate inserts and solving special loading problems. Molders customarily extrude these materials into a ribbon of a specific size, which is then cut into preforms before molding. Whereas granular alkyds are rather diversified in their various applications, putty has found widespread use in one major application: molded encapsulation of small electronic components, such as mica, polyester film, and paper capacitors, deposited carbon resistors, small coils, and transformers.

The purpose here is to insulate the components electrically, as well as to seal out moisture. Use of alkyds has become especially popular because of their excellent electrical and thermal properties, which resulted in high functional efficiency of the unit in a minimum space, coupled with low-pressure molding requirements, which prevent distortion of the subassembly during molding.

Glass Fiber-Reinforced Types

This type of alkyd-molding compound is used in a large number of applications requiring high mechanical strength as well as electrical insulating properties. Glass fiber-reinforced alkyds can be either compression or plunger molded permitting a wide variety of types of applications, ranging from large circuit breaker housings to extremely delicate electronic components.

Other Types of Alkyd-Molding Compounds

Halogen- and/or phosphorous-bearing alkyd-molding compounds with antimony trioxide added provide improved flame resistance. Other flame-resistant compounds are available that do not contain halogenated resins. Many grades are Underwriters' Laboratories rated at 94 V-0 in sections under 1/16 in. Flammability ratings depend on specific formulations, however, and can vary from 94 HB to V-0. Flammability ratings also vary with section thickness.

Glass- and asbestos-filled compounds have better heat resistance than the cellulose-modified types. Depending on type, alkyds can be used continuously to 350°F and, for short periods, to 450°F.

Alkyd molding compounds retain their dimensional stability and electrical mechanical properties over a wide temperature range.

Alkylation

(1) A chemical process in which an alkyl radical is introduced into an organic compound by substitution or addition. (2) A refinery process for chemically combining isoparaffin with olefin hydrocarbons.

Alligator Skin

See *orange peel*.

Alligatoring

(1) Pronounced wide cracking over the entire surface of a coating having the appearance of alligator hide. (2) The longitudinal splitting of flat slabs in a plane parallel to the rolled surface. Also called fish mouthing.

All-Metal Package

A hybrid circuit package made solely of metal, excluding glass or ceramic. Its main applications are with microwave modules and large plug-ins.

Allomeric

Different substances having the same crystallographic structure.

Allomorphous

Having different crystalline forms for a given composition.

Allophanate

Reactive product of an isocyanate and the hydrogen atoms in a urethane.

Alloprene

Chlorinated rubber.

Allotriomorphic Crystal

A crystal whose lattice structure is normal but whose external surfaces are not bounded by regular crystal faces; rather, the external surfaces are impressed by contact with other crystals or another surface such as a mold wall or are irregularly shaped because of non-uniform growth. Compare with *idiomorphic crystal*.

Allotropic

Occurring in two or more solid forms having differing physical characteristics and where the change is reversible. If the change is not reversible, polymorphism is the usual term.

Allotropy

(1) A near synonym for *polymorphism*. Allotropy is generally restricted to describing polymorphic behavior and elements,

terminal phases, and alloys whose behavior *closely parallels* that of the predominant constituent element. (2) The existence of a substance, especially an element, and two or more physical states (e.g., crystals). See also *graphite*.

Allowance

(1) The specified difference in limiting sizes (minimum clearance or maximum interference) between mating parts, as computed arithmetically from the specified dimensions and tolerances of each part. (2) In a foundry, the specified clearance. See also *tolerance*.

Allowed (Energy) Bands

The band of energy in which the valence electrons of a metal crystal are allowed to exist. Individual bands may be empty or partially or completely filled, and they are separated by forbidden bands in which the electrons cannot normally exist other than to jump across. See also *band theory* and *semiconductors*.

Alloy

(1) A substance having metallic properties and being composed of two or more chemical elements of which at least one is a *metal*. (2) To make or melt an alloy. (3) In plastics, a blend of polymers or copolymers with other polymers or elastomers under selective conditions, for example, styrene-acrylonitrile. Also called polymer blend.

The term implies that the additional element has been introduced deliberately with the intention of improving some characteristic of the material. Brass, bronze, steel, and sterling silver are examples of alloys. Steel was an alloy of iron with a small but vital carbon content so the term “alloy steel” implies the addition of further elements such as nickel, chromium, and molybdenum to improve specific properties. The term is used colloquially, as in “alloy wheels” when referring to aluminum probably as a corruption of the long-established casual conversational use in some industries of “alley” referring to aluminum in either its pure or alloy form. The potential for confusion is obvious.

Alloys are used because they have specific properties or production characteristics that are most attractive than those of the pure, elemental metals. For example, some alloys possess high strength, others have low melting points, others are refractory with high melting temperatures, some are especially resistant to corrosion, and others have desirable magnetic, thermal, or electrical properties. These characteristics arise from both the internal and the electronic structure of the alloy. In recent years, the term *plastic alloy* also has been applied to plastics.

Metal alloys are more specifically described with reference to the major element by weight, which is also called the base metal or parent metal. Thus, the terms “aluminum alloy,” “copper alloy,” etc. Elements present in lesser quantities are called alloying elements. When one or more alloying elements are present in substantial quantity or, regardless of their amount, have a pronounced effect on the alloy, they, too, may be reflected in generic designations.

Metal alloys are also often designated by trade names or by trade association or society designations. Among the more common of the latter are the three-digit designations for the major families of stainless steels and the four-digit ones for aluminum alloys.

Structurally, there are two kinds of metal alloys—single phase and multiphase. Single-phase alloys are composed of crystals with the same type of structure. They are formed by “dissolving” together different elements to produce a solid solution. The crystal structure of a solid solution is normally that of the base metal.

A

In contrast to single-phase alloys, multiphase alloys are mixtures rather than solid solutions. They are composed of aggregates of two or more different phases. The individual phases making up the alloy are different from one another in their composition or structure. Solder, in which the metals lead and tin are present as a mechanical mixture of two separate phases, is an example of the simplest kind of multiphase alloy. In contrast, steel is a complex alloy composed of different phases, some of which are solid solutions. Multiphase alloys far outnumber single-phase alloys in the industrial material field, chiefly because they provide greater property flexibility. Thus, properties of multiphase alloys are dependent upon many factors, including the composition of the individual phases, the relative amounts of the different phases, and the positions of the various phases relative to one another.

When two different thermoplastic resins are plastic, alloy is obtained. Alloying permits resin polymers to be blended that cannot be polymerized. Not all plastics are amenable to alloying. Only resins that are compatible with each other—those that have similar melt traits—can be successfully blended.

Types of Alloys

Bearing Alloys

These alloys are used for metals that encounter sliding contact under pressure with another surface; the steel of a rotating shaft is a common example. Most bearing alloys contain particles of a hard intermetallic compound that resists wear. These particles, however, are embedded in a matrix of softer material that adjusts to the hard particles so that the shaft is uniformly loaded over the total surface. The most familiar bearing alloy is Babbitt metal, which contains 83%–91% tin (Sn); the remainder is made up of equal parts of antimony (Sb) and copper (Cu), which form hard particles of the compounds SbSn and CuSn in a soft tin matrix. Other bearing alloys are based on cadmium (Cd), copper, or silver (Ag). For example, an alloy of 70% copper and 30% lead (Pb) is used extensively for heavily loaded bearings. Bearings made by powder metallurgy techniques are widely used. These techniques are valuable because they permit the combination of materials that are incompatible as liquids, for example, bronze and graphite. Powder techniques also permit controlled ferocity within the bearing so that they can be saturated with oil before being used, the so-called oilless bearings.

Corrosion-Resisting Alloys

Certain alloys resist corrosion because they are noble metals. Among these alloys are the precious metal alloys, which will be discussed separately. Other alloys resist corrosion because a protective film develops on the metal surface. This passive film is an oxide that separates the metal from the corrosive environment. Stainless steels and aluminum alloys exemplify metals with this type of protection. Stainless steels, which are iron alloys containing more than 12% chromium (Cr) and 8% nickel (Ni), are the best known and possess a high degree of resistance to many corrosive environments. Aluminum (Al) alloys gain their corrosion-deterring characteristics by the formation of a very thin surface layer of aluminum oxide (Al_2O_3), which is inert to many environmental liquids. This layer is intentionally thickened by a commercial anodizing processes to give a more permanent Al_2O_3 coating. Monel, an alloy of approximately 70% nickel and 30% copper, is a well-known corrosion-resisting alloy that also has high strength. Another nickel-base alloy is Inconel, which contains 14% chromium and 6% iron (Fe). The bronzes, alloys of copper and tin, also may be considered to be corrosion resistant.

Dental Alloys

Amalgams are predominantly alloys of silver and mercury, but they may contain minor amounts of tin, copper, and zinc for hardening purposes, for example, 33% silver, 52% mercury, 12% tin, 2% copper, and less than 1% zinc. Liquid mercury is added to a powder of a precursor alloy of the other metals. After compaction, the mercury diffuses into the silver-base metal to give a completely solid alloy. Gold-base dental alloys are preferred over pure gold because gold is relatively soft. The most common dental gold alloy contains gold (80%–90%), silver (3%–12%), and copper (2%–4%). For higher strengths and hardnesses, palladium and platinum (up to 3%) are added, and the copper and silver are increased so that the gold content drops 60%–70%. Vitallium, an alloy of cobalt (65%), chromium (5%), and molybdenum (3%), and nickel (3%), and other corrosion-resistant alloys are used for bridge work and special applications.

Die-Casting Alloys

These alloys have melting temperatures low enough so that in the liquid form they can be injected under pressure into steel dies. Such castings are used for automotive parts and for office and household appliances that have moderately complex shapes. This processing procedure eliminates the need for expensive machining and forming operations. Most die castings are made from zinc-base or aluminum-base alloys. Magnesium-base alloys also find some application when weight reduction is paramount. Low-melting alloys of lead and tin are not common because they lack the necessary strength for the aforementioned applications. A common zinc-base alloy contains approximately 4% aluminum and up to 1% copper. These additions provide a second phase in the metal to give added strength. The alloy must be free of even minor amounts (less than 100 ppm) of impurities such as lead, cadmium, or tin, because impurities increase the rate of corrosion. Common alumina-base alloys contain 5%–12% silicon, which introduces hard-silicon particles into the tough alumina matrix. Unlike zinc-base alloys, aluminum-base alloys cannot be electroplated; however, they may be burnished or coated with enamel or lacquer.

Advances in high-temperature die-mold materials have focused attention on the die casting of copper-base and iron-base alloys. However, the high casting temperatures introduce costly production requirements, which must be justified on the basis of reduced machining costs.

Eutectic Alloys

In certain alloy systems, a liquid of a fixed composition freezes to form a mixture of two basically different solids or phases. An alloy that undergoes this type of solidification process is called a eutectic alloy. A typical eutectic alloy is formed by combining 28.1% of copper with 71.9% of silver. A homogeneous liquid of this composition on slow cooling freezes to form a mixture of particles of nearly pure copper embedded in a matrix (background) of nearly pure silver.

The advantageous mechanical properties inherent in composite materials such as plywood composed of sheets or lamellae of wood bonded together and fiberglass in which glass fibers are used to reinforce a plastic matrix have been known for many years. Attention is being given to eutectic alloys because they are basically natural composite materials. This is particularly true when they are directionally solidified to yield structures with parallel plates of the two phases (lamellar structure) or long fibers of one phase embedded in the other phase (fibrous structure). Directionally solidified eutectic alloys are being given serious consideration for use in fabricating jet engine turbine blades. For this purpose, eutectic alloys that freeze to form tantalum carbide (TaC) fibers in a matrix of a cobalt-rich alloy have been heavily studied.

Fusible Alloys

These alloys generally have melting temperatures below that of tin (450°F or 232°C) and in some cases as well as 120°F (50°C). Using eutectic compositions of metals such as lead, cadmium, bismuth, tin, antimony, and indium achieves these low melting temperatures. These alloys are used for many purposes, for example, in fusible elements in automatic sprinklers, forming and stretching dies, filler for thin-walled tubing that is being bent, and anchoring dies, punches, and parts being machined. Alloys rich in bismuth were formally used for type metal because these low-melting metals exhibited a slight expansion on solidification, thus replicating the font perfectly for printing and publication.

High-Temperature Alloys

Energy conversion is more efficient at high temperatures than at low; thus the need in power-generating plants, jet engines, and gas turbines for metals that have high strengths at high temperatures is obvious. In addition to having strength, these alloys must resist oxidation by fuel-air mixtures and steam vapor. At temperatures up to about 1380°F (750°C), the austenitic stainless steels (18% Cr–8% Ni) serve well. An additional 180°F (100°C) may be realized if the steels also contain 3% molybdenum. Both nickel-base and copper-base alloys, commonly categorized as superalloys, may serve useful functions up to 2000°F (1100°C). Nichrome, a nickel-base alloy containing 12%–15% chromium and 25% iron, is a fairly simple superalloy. More sophisticated alloys invariably contain five, six, or more components, for example, an alloy called Rene, 41 contains approximately 9% Cr, 1.5% Al, 3% Ti, 11% Co, 10% Mo, 3% Fe, 0.1% C, 0.005% B, and the balance Ni. Other alloys are equally complex. The major contributor to strengthen these alloys is the solution-precipitate phase of Ni₃(TiAl). It provides strength because it is coherent with the nickel-rich phase. Cobalt-base superalloys maybe even more complex and generally contain carbon, which combines with the tungsten (W) and chromium to produce carbides that serve as the strengthening agent. In general, the cobalt-base superalloys are more resistant to oxidation than the nickel-based alloys are, but they are not as strong. Molybdenum-base alloys have exceptionally high strength at high temperatures, but their brittleness at lower temperatures and their poor oxidation resistance at high temperatures have limited their use. However, coatings permit the use of such alloys in an oxidizing atmosphere, and they are finding increased application. A group of materials called cermets, which are mixtures of metals and compounds such as oxides and carbides, have high strength at high temperatures, and although their ductility is low, they have been found to be usable. One of the better-known cermets consists of a mixture of TiC and nickel, the nickel acting as a binder or cement for the carbide.

Joining Alloys

Metals are bonded by three principal procedures: welding, brazing, and soldering. Welded joints melt the contact region of the adjacent metal; thus, the filler material is chosen to approximate the composition of the parts being joined. Brazing and soldering alloys are chosen to provide filler metal with an appreciably lower melting point than that of the joined parts. Typically, brazing alloys melt above 750°F (400°C), whereas solders melt at lower temperatures. A 57% Cu–42% Zn–1% Sn brass is a general-purpose alloy for brazing steel and many nonferrous metals. A Si–Al eutectic alloy is used for brazing aluminum, and an aluminum-containing magnesium eutectic alloy brazes magnesium parts. The most common solders are based on Pb–Sn alloys. The prevalent 60% Sn–40% Pb alloy has a range of solidification and is thus preferred as a wiping solder by plumbers.

Light-Metal Alloys

Aluminum and magnesium, with densities of 2.7 and 1.75 g/cm³, respectively, are the basis for most of the light-metal alloys. Titanium (4.5 g/cm³) may also be regarded as a light-metal alloy if comparisons are made with metal such as steel and copper. Aluminum and magnesium must be hardened to receive extensive application. Age-hardening processes are used for this purpose. Typical alloys are 90% Al–10% Mg, 95% Al–5% Cu, and 90% Mg–10% Al. Ternary (three element) and more complex alloys are very important light-metal alloys because of their better properties. The Al–Zn–Mg system of alloys, used extensively in aircraft applications, is a prime example of one such alloys system.

Low-Expansion Alloys

This group of alloys includes Invar (64% Fe–36% Ni), the dimensions of which do not vary over the atmospheric temperature range. It has special applications in watches and other temperature-sensitive devices. Glass-to-metal seals for electronic and related devices require a matching of the thermal-expansion characteristics of the two materials. Kovar (54% Fe–29% Ni–17% Co) is widely used because its expansion is low enough to match that of glass.

Magnetic Alloys

Soft and hard magnetic materials involve two distinct categories of alloys. The former consists of materials used for magnetic cores of transformers fan motors and must be magnetized and demagnetized easily. For AC applications, silicon ferrite is commonly used. This is an alloy of iron containing as much as 5% silicon. The silicon has little influence on the magnetic properties of the iron, but it increases the electric resistance appreciably and thereby decreases the core loss by induced currents. A higher magnetic permeability, and therefore greater transformer efficiency, is achieved if these silicon steels are grain oriented so that the crystal axes are closely aligned with the magnetic field. Permalloy (78.5% Ni–21.5% Fe) and some comparable cobalt-base alloys have very high permeabilities at low field strengths and thus are used in the communications industry. Ceramic ferrites, although not strictly alloys, are widely used in high-frequency applications because of their low electrical conductivity and negligible induced energy losses in the magnetic field. Permanent or hard magnets may be made from steels that are mechanically hardened, either by deformation or by quenching. Some precipitation-hardening, iron-base alloys are widely used for magnets. Typical of these are the Alnicos, for example, Alnico-4 (55% Fe–28% Ni–12% Al–5% Co). Since these alloys cannot be forged, they must be produced in the form of castings. Hard magnets are being produced from alloys of cobalt and the rare earth type of metals. The compound RCo₅, where R is samarium (Sm), lanthanum (La), cerium (Ce), and so on, has extremely high coercivity.

Precious-Metal Alloys

In addition to their use in coins and jewelry, precious metals such as silver, gold, and the heavier platinum (Pt) metals are used extensively in electrical devices in which contact resistances must remain low, in catalytic applications to aid chemical reactions, and in temperature-measuring devices such as resistance thermometers and thermocouples. The unit of alloy impurity is commonly expressed in karats, when each karat is 1/24 of the part. The most common precious-metal alloy is sterling silver (92.5% Ag, with the remainder being unspecified, but usually copper). Copper is very beneficial in that it makes the alloy harder and stronger than pure silver. Yellow gold is an Au–Ag–Cu alloy with an approximately 2:1:1 ratio. White gold is an alloy that ranges from 10 to 18 karats, the remainder being additions of nickel,

silver, or zinc, with change of color from yellow to white. The alloy 87% platinum–13% rhodium (Rh), when joined with pure platinum, provides a widely used thermocouple for temperature measurements in the 1832°F–3000°F (1002°C–1650°C) temperature range.

Shape Memory Alloys

These alloys have a very interesting and desirable property. In a typical case, a metallic object of a given shape is cooled from a given temperature T_1 , two or lower temperature T_2 , where it is deformed to change its shape. Upon reheating from T_2 to T_1 , the shape change accomplished at T_2 is recovered so that the object returns to its original configuration. This thermoelastic property of the shape memory alloys is associated with the fact that they undergo a martensitic phase transformation (i.e., a reversible change in crystal structure that does not involve diffusion) when they are cooled or heated between T_1 and T_2 .

For a number of years, the shape memory materials were essentially scientific curiosities. Among the first alloys shown to possess these properties was one of gold alloyed with 47.5% cadmium. Considerable attention has been given to an alloy of nickel and titanium known as *nitinol*. The interest in shape memory alloys has increased because it has been realized that these alloys are capable of being employed in a number of useful applications. One example is for thermostats; another is for couplings on hydraulic lines or electrical circuits. The thermoelastic properties can also be used, at least in principle, to construct heat engines that will operate over a small temperature differential and will thus be of interest in the area of energy conversion.

Thermocouple Alloys

These include *chromel*, containing 90% Ni and 10% Cr, and *alumel*, containing 94% Ni, 2% Al, 3% Cr, and 1% Si. These two alloys together form the widely used *chromel-alumel* thermocouple, which can measure temperatures up to 2200°F (1204°C). Another common thermocouple alloy is *constantan*, consisting of 45% Ni and 55% Cu. It is used to form iron–constantan and copper–constantan couples, used at lower temperatures. For precise temperature measurements and for measuring temperatures up to 3000°F (1650°C), thermocouples are used in which one metal is platinum and the other metal is platinum plus either 10% or 13% rhodium.

Prosthetic Alloys

Prosthetic alloys are alloys used in internal prostheses, that is, surgical implants such as artificial hips and knees. External prostheses are devices that are worn by patients outside the body; alloy selection criteria are different from those for internal prostheses. In the United States, surgeons use about 250,000 artificial hips and knees and about 30,000 dental implants per year.

Alloy selection criteria for surgical implants can be stringent primarily because of biochemical and chemical aspects of the service environment. Mechanically, the properties and shape of an implant must meet anticipated functional demands, for example, hip joint replacements are routinely subjected to cyclic forces that can be several times body weight. Therefore, intrinsic mechanical properties of an alloy, for example, elastic modulus, yield strength, fatigue strength, ultimate tensile strength, and wear resistance, must all be considered. Similarly, because the pH and ionic conditions within a living organism define a relatively hostile corrosion environment for metals, corrosion properties are an important consideration. Corrosion must be avoided not only because of alloy deterioration but also because of the possible physiological effects of harmful or even cytotoxic corrosion products that may be released into the body. (Study of the biological effects of biomaterials is a broad subject in itself, often referred to as biocompatibility.) The corrosion

resistance of all modern alloys stems primarily from strongly adherent and passivating surface oxides, such as TiO_2 on titanium-base alloys and Cr_2O_3 on cobalt-based alloys.

The most widely used prosthetic alloys therefore include high strength, corrosion-resistant ferrous, cobalt-base, or titanium-base alloys. Examples include cold-worked stainless steel; cast Vitallium, a wrought alloy of cobalt, nickel, chromium, molybdenum, and titanium; titanium alloyed with aluminum and vanadium; and commercial-purity titanium. Specifications for nominal alloy compositions are designated by the American Society for Testing and Materials (ASTM).

Prosthetic alloys have a range of properties. Some are easier than others to fabricate into the complicated shapes dictated by anatomical constraints. Fabrication techniques include investment casting (solidifying molten metal in a mold), forging (forming metal by deformation), machining (forming by machine shop processes, including computer-aided design and manufacturing), and hot isostatic pressing (compacting fine powders of alloy into desired shapes under heat and pressure). Cobalt-base alloys are difficult to machine and are therefore usually made by casting or hot isostatic pressing. Some newer implant designs are porous coated, that is, they are made from the standard ASTM alloys but are coated with alloy beads or mesh applied to the surface by centering or other methods. The rationale for such coatings is implant fixation by bone ingrowth.

Some alloys are modified by nitriding or ion implantation of surface layers of enhanced service properties. A key point is that prosthetic alloys of identical composition can differ substantially in terms of structure and properties, depending on fabrication history. For example, the fatigue strength approximately triples for hot isostatically pressing versus as-cast Co–Cr–Mo alloy, primarily because of a much smaller grain size in the microstructure of the former.

No single alloy is vastly superior to all others, existing prosthetic alloys have all been used in successful and, indeed, unsuccessful implant designs. Alloy selection is only one determinant of performance of the implanted device.

Superconducting Alloys

Superconductors are materials that have zero resistance to the flow of electric current at low temperatures. There are more than 6000 elements, alloys, and compounds that are known superconductors. This remarkable property of zero resistance offers unprecedented technological advances such as the generation of intense magnetic fields. Realization of these new technologies requires development of specifically designed superconducting alloys and composite conductors. An alloy of niobium and titanium (NbTi) has a great number of applications and superconductivity; it becomes superconducting at 9.5 K (critical superconducting temperature, T_c). This alloy is preferred because of its ductility and its ability to carry large amounts of current at high magnetic fields, represented by $J_c(H)$ (where J_c is the critical current and H is a given magnetic field), and still retains its superconducting properties. Brittle compounds with intrinsically superior superconducting properties are also being developed for magnet applications. The most promising of these are compounds of niobium and strontium (Nb_3Sn), vanadium and gallium (V_3Ga), niobium and germanium (Nb_3Ge), and niobium and aluminum (Nb_3Al), which have higher T_c (15–23 K) and higher $J_c(H)$ than NbTi.

Superconducting materials possess other unique properties such as magnetic flux quantization and magnetic field–modulated supercurrent flow between two slightly separated superconductors.

These properties form the basis for electronic applications of superconductivity such as high-speed computers or ultrasensitive magnetometers. Development of these applications began using lead or niobium in bulk form, but the emphasis then was transferred

to materials deposited in the thin-film form. PbIn and PbAu alloys are more desirable than pure lead films, as they are more stable. Improved vacuum deposition systems eventually led to the use of pure niobium films as they, in turn, were more stable than lead alloy films. Advances in thin-film synthesis techniques led to the use of the refractory compound niobium nitride (NbN) in electronic applications. This compound is very stable and possesses a higher T_c (15 K) than either lead or niobium.

Novel high-temperature superconducting materials have revolutionary impact on superconductivity and its applications. These materials are ceramic, copper oxide-based materials that contain at least four and as many as six elements. Typical examples are yttrium-barium-copper-oxygen (T_c [93 K]), bismuth-strontium-calcium-copper-oxygen (T_c [110 K]), and thallium-barium-calcium-copper (T_c [125 K]). These materials become superconducting at such high temperatures that refrigeration is simpler, more dependable, and less expensive. Much research and development has been done to improve the technologically important properties such as J_c (H), chemical and mechanical stability, and device-compatible processing procedures. It is anticipated that the new compounds will have a significant impact in the growing field of superconductivity.

Alloy Plating

The codeposition of two or more metallic elements. The electrodeposition of a coating comprising two metals such as copper and zinc to produce a brass plate. The two metals may be supplied from a single alloy anode or from individual anodes.

Alloy Powder; Alloyed Powder

A metal powder consisting of at least two constituents that are partially or completely alloyed with each other.

Alloy Steel

Steel containing specified quantities of alloying elements (other than carbon and the commonly accepted amounts of manganese, copper, silicon, sulfur, and phosphorus) within the limits recognized for constructional alloy steels, added to affect changes in mechanical or physical properties.

In general, the term applies to all steels exceeding the limits of manganese, silicon, and copper of carbon steels or which contain other alloying ingredients. Alloy steels often take the name of the alloying element or elements having the greatest influence on their performance characteristics or the name of the key characteristic, processing mechanism, or application. Thus, the prevalence of such terms as nickel steels; stainless, or corrosion-resistant, steels; maraging steels; precipitation-hardening steels; tool steels; valve steels; etc. Usually, however, the term excludes high-alloy steels and refers instead to the standard alloy steels of the American Iron and Steel Institute (AISI) and Society of Automotive Engineers (SAE) International, which contain low to moderate amounts of alloying elements, usually less than 5% total. The AISI or SAE designations of these steels are usually noted by four numerals—13XX–91XX. The first two numerals pertain to a specific alloying element or elements, and the last two numerals indicate carbon content in hundredths of 1%. Sometimes, three numerals are used to denote carbon content, and a letter, such as B for boron and L for lead, follows the first two numerals to indicate an alloying element not indicative of the first two numerals. A letter prefix is used occasionally to designate special furnace practice used to make the steel, and the suffix H is used to designate steels made to specific hardenability requirements. A three-numeral system, 9XX, is commonly used to

designate high-strength, low-alloy (HSLA) steels, some of which are also called microalloyed steels because of the small amount of alloying elements, with the last two numerals indicating minimum tensile yield strength in 1000 lb/in.² (6.895 MPa). Although most alloy steels are heat treated by users and extremely high levels of strength and toughness can be achieved, HSLA steels are typically supplied to specific strength levels and are not heat treated by users.

Alloy Structures

Metals in actual commercial use are almost exclusively alloys, and not pure metals since it is possible for the designer to realize an extensive variety of physical properties in the product by varying the metallic composition of the alloy. As a case in point, commercially pure or cast iron is very brittle because of the small amount of carbon impurity always present, whereas the steels are much more ductile, with greater strength and better corrosion properties. In general, the highly purified single crystal of a metal is very soft and malleable, with high electrical conductivity, whereas the alloy is usually harder and may have a much lower conductivity. The conductivity will vary with the degree of order of the alloy, and the hardness will vary with the particular heat treatment used.

The basic knowledge of structural properties of alloys is still in large part empirical, and indeed, it will probably never be possible to derive formulas that will predict which metals to mix in a certain proportion and with a certain heat treatment to yield a specified property or set of properties. However, a set of rules exists that describes the qualitative behavior of certain groups of alloys. These rules are statements concerning the relative sizes of constituent atoms, for alloy formation, and concerning what kinds of phases to expect in terms of the valence of the constituent atoms. The rules were discovered in a strictly empirical way, and for the most part, the present theoretical understanding of alloys consists of rudimentary theories that describe how the rules arise from the basic principles of physics. These rules were proposed by W. Hume-Rothery concerning the binary substitutional alloys and phase diagrams.

Alloy System

A complete series of compositions produced by mixing in all proportions any group of two or more components, at least one of which is a metal.

Alloying Element

An element added to and remaining in a metal that changes structure and properties.

All-Position Electrode

In arc welding, a filler-metal electrode for depositing weld metal in the flat, horizontal, overhead, and vertical positions.

Alluvial Tin

This or other materials deposited on the beds of rivers and areas of slow flow, having been transported by the stream from locations where it was eroded from the rocks.

All-Weld-Metal Test Specimen

A test specimen wherein the portion being tested is composed wholly of weld metal.

A

Allylics (Diallyl Phthalate Plastics)

Allylics are thermosetting materials developed since World War II. The most important of these are diallyl phthalate (DAP) and diallyl isophthalate (DAIP), which are currently available in the form of monomers and prepolymers (resins). Both DAP and DAIP are readily converted to thermoset-molding compounds and resins for preimpregnated glass cloth and paper. Allyls are also used in cross-linking agents for unsaturated polyesters.

DAP resin is the first all-allylic polymer commercially available as a dry, free-flowing white powder. Chemically, DAP is a relatively linear partially polymerized resin that softens and flows under heat and pressure (as in molding and laminating) and cross-links to a 3D insoluble thermoset resin during curing. This family of thermoset resins made by *addition polymerization* of compounds containing the group $\text{CH}_2: \text{CH}-\text{CH}_2$, such as esters of allyl alcohol and dibasic acids. They are available as monomers, partially polymerized prepolymers, or molding compounds. Other members of the family besides the two mentioned earlier are diallyl maleate and diallyl chloroendate.

Properties

In preparing the resin, DAP is polymerized to a point where almost all the change in specific gravity has taken place. Final cure, therefore, produces very little additional shrinkage. In fact, DAP is cured by polymerization without water formation.

Allylic resins enjoy certain specific advantages over other plastics, which make them of interest in various special applications. Allylics

exhibit superior electrical properties under severe temperature and humidity conditions. These good electrical properties (insulation resistance, low loss factor, arc resistance, etc.) are retained despite repeated exposure to high heat and humidity. DAP resin is resistant to 155°C–180°C temperatures, and the DAIP resin is good for continuous exposures up to 206°C–232°C temperatures. Allylic resins exhibit excellent postmold dimensional stability, low moisture absorption, good resistance to solvents, acids, alkalies, weathering, and wet and dry abrasion. They are chemically stable, have good surface finish, mold well around metal inserts, and can be formulated in pastel colors with excellent color retention at high temperatures.

DAP resin currently finds major use in (1) molding and (2) industrial and decorative laminates. Both applications utilize the desirable combination of low shrinkage, absence of volatiles, and superior electrical and physical properties common to DAP.

Molding Compounds

Compounds based on allyl prepolymers are reinforced with fibers (glass, polyester, or acrylic) and filled with particulate materials to improve properties. Glass fiber imparts maximum mechanical properties, acrylic fiber provides the best electrical properties, and polyester fiber improves impact resistance and strength in thin sections. Compounds can be made in a wide range of colors because the resin is essentially colorless. See Table A.9.

Prepregs (preimpregnated glass cloth) based on allyl prepolymers can be formulated for short cure cycles. They contain no toxic

TABLE A.9
Properties of DAP Molding Compounds

ASTM Test	Property	Filler			Arc-Track Resistant
		Polyester	Long Glass	Short Glass	
Physical					
D792	Specific gravity	1.39–1.42	1.70–1.90	1.6–1.8	1.87
D792	Specific volume (in. ³ /lb)	19.96–19.54	17.90–16.32	17.34–15.42	14.84
D570	Water absorption, 24 h, 1/8-in. thk (%)	0.2	0.05–0.2	0.05–0.2	0.14
Mechanical					
D638	Tensile strength (psi)	5,000	9,000	7,000	7,000–10,000
D790	Flexural strength (psi)	11,500–12,500	18,000	16,000	24,000
D790	Flexural modulus (10 ⁵ psi)	6.4	16	17	19

additives, and they offer long storage stability and ease of handling and fabrication. Properties such as flame resistance can be incorporated. The allyl prepolymers contributed excellent chemical resistance and good electrical properties.

Other molding powders are compounded of DAP resin, DAP monomer, and various fillers like asbestos, Orlon, Dacron, cellulose, glass, and other fibers. Inert fillers used include ground quartz and clays, calcium carbonate, and talc.

Allyl moldings have low-mold shrinkage and postmold shrinkage—attributed to their nearly complete addition reaction in the mold—and have excellent stability under prolonged or cyclic heat exposure. Advantages of allyl systems over polyesters are freedom from styrene odor low toxicity, low evaporation losses during evacuation cycles, though subsequent oozing or bleed out, and long-term retention of electrical insulation characteristics.

Applications

Uses of such DAP-molding compounds are largely for electrical and electronic parts, connectors, resistors, panels, switches, and insulators. Other applications for molding compounds include appliance handles, control knobs, dinnerware, and cooking equipment.

Decorative laminates containing DAP resin can be made from glass cloth (or other woven and nonwoven materials), glass mat, or paper. Such laminates may be bonded directly to a variety of rigid surfaces at lower pressures (50–300 psi) than generally required for other plastic laminates. A short hot-to-hot cycle is employed, and press platens are always held at curing temperatures. DAP laminates can, therefore, be used to give a permanent finish to high-grade wood veneers (with a clear overlay sheet) or to upgrade low-cost core materials (by means of a patterned sheet).

Allyl prepolymers are particularly suited for critical electronic components that serve in severe environmental conditions. Chemical inertness qualifies the resins for molded pump impellers and other chemical-processing equipment. Their ability to withstand steam environments permits uses in sterilizing and hot-water equipment. Because of their excellent flow characteristics, DAP compounds are used for parts requiring extreme dimensional accuracy. Modified resin systems are used for encapsulation of electronic devices such as semiconductors and sealants for metal castings.

A major application area for allyl compounds is electrical connectors, used in communications, computer, and aerospace systems. The high thermal resistance of these materials permits their use in vapor-phase soldering operations. Uses for prepolymers include arc-track-resistant compounds for switchgear and television components. Other representative uses are for insulators, encapsulating shells, potentiometer components, circuit boards, junction boxes, and housings.

DAP and DAIP prepreps are used to make lightweight, intricate parts such as radomes, printed circuit boards, tubing, ducting, and aircraft parts. Another use is in copper-clad laminates for high-performance printed circuit boards.

Alnico

See Alcomax.

Alpha

The various phases occurring in our systems are designated by Greek letters, α , β , γ , etc., respectively, alpha, beta, gamma, etc. Alpha usually refers to the primary solid solution in any system. See also *Greek*.

Alpha (α) Cellulose

A very pure cellulose prepared by special chemical treatment.

Alpha (α) Loss Peak

In dynamic mechanical or dielectric measurement, the first peak in the damping curve below the melt, in order of decreasing temperature or increasing frequency.

Alpha Brass

A solid-solution phase of one or more alloying elements and copper having the same crystal lattice as copper.

Alpha Brasses

Brasses containing up to about 37% zinc. They are single, alpha phase and are readily cold worked following initial hard working.

Alpha Case

The oxygen-, nitrogen-, or carbon-enriched α -stabilized surface in titanium resulting from elevated temperature exposure. See also *alpha stabilizer*.

Alpha Double Prime (α'') (Orthorhombic Martensite)

A supersaturated, nonequilibrium orthorhombic phase formed by a diffusionless transformation of the β phase in certain titanium alloys. It is often difficult to distinguish from a acicular α , although the latter is usually less well defined and frequently has curved, instead of straight sides.

Alpha Ferrite

See *ferrite*.

Alpha Iron

The body-centered cubic form of pure iron, stable below 910°C (1670°F).

Alpha Model 1

A type of wear-testing machine consisting of a conforming or flat-faced block pressed vertically downward by a deadweight loading arrangement against the circumference of a hardened steel ring that is rotating on a shaft.

Alpha Particles

Subatomic particles comprising two protons and two neutrons, that is, the helium nucleus, and hence positively charged. They have relatively low penetrating power.

Alpha Process

A *shell molding* and core making method in which a thin resin-bonded shell is baked with the less expensive, highly permeable material.

A

Alpha Stabilizer

An alloying element in titanium that dissolves preferentially in the α and $\alpha - \beta$ transformation temperature.

Alpha Transus

The temperature that designates the phase boundary between the α and $\alpha + \beta$ fields in titanium alloys.

Alpha–Beta Brasses

Brasses that contain about 40% zinc. They are duplex, alpha plus beta, and are readily hot worked but will accept only a small amount of cold work.

Alpha–Beta Structure

A titanium microstructure containing α and β as the principal phases at a specific temperature. See also *beta*.

Alsifer

A deoxidizer (20Al, 40Si, 40Fe) used for steel.

Alternate Immersion Test

A corrosion test in which the specimens are intermittently exposed to a liquid medium at definite time intervals.

Alternate Polarity Operation

A resistance welding process variation in which succeeding welds are made with pulses of alternating polarity.

Alternating Copolymer

A copolymer in which each repeating unit is joined to another repeating unit in the polymer chain (–A–B–A–B).

Alternating Current Resistance

The resistance offered by any circuit to the flow of alternating current.

Alternating Stress Amplitude

A test parameter of a dynamic fatigue test; one-half the algebraic difference between the maximum and minimum stress in one cycle.

Alum

A colorless to white crystalline potassium aluminum sulfate, $KAl(SO_4)_2 \cdot 12H_2O$, or $\{KAl(H_2O)_6\}SO_4 \cdot 6H_2O$, occurring naturally as the mineral kalunite, or kalinite, and in combination as the mineral alunite. It is also called potash alum to distinguish it from other forms. It has a sweetish taste and is very astringent. It is used as an additive in the leather and textile industries, in sizing paper, as a mordant in dyeing, in medicines as an astringent, and baking powder. It is made commercially by reacting bauxite with sulfuric acid and then potassium sulfate. It is an important water-purifying agent. From a water solution, it crystallizes out, forming positively charged particles, which attract the negatively charged organic impurities, thus purifying the water as they settle out.

Alumel

An alloy of nickel with about 2.5% manganese, 2% aluminum, and 1% silicon widely used in conjunction with chromel for pyrometric thermocouples.

Alumina

The oxide of aluminum is Al_2O_3 . The natural crystalline mineral is called corundum, but the synthetic crystals used for abrasives are designated usually as aluminum oxide or marketed under trade names. For other uses and as a powder, it is generally called alumina. It is widely distributed in nature in combination with silica and other minerals and is an important constituent of the clays for making porcelain, bricks, pottery, and refractories.

The crushed and graded crystals of alumina when pure are nearly colorless, but the fine powder is white. Off colors are due to impurities. American aluminum oxide used for abrasives is at least 99.5% pure, in nearly colorless crystals melting at 2050°C. The chief uses for alumina are for the production of aluminum metal and for abrasives, but it is also used for ceramics, refractories, pigments, catalyst carriers, and in chemicals.

Aluminum oxide crystals are normally hexagonal and are minute in size. For abrasives, the grain sizes are usually from 100 to 600 mesh. The larger grain sizes are made up of many crystals, unlike the single-crystal large grains of SiC. The specific gravity is about 3.95, and a hardness is up to 2000 Knoop.

There are two kinds of ultrafine alumina abrasive powder. Type A is alpha alumina with hexagonal crystals with particle size of 0.3 μm , density 4.0, and hardness 9 Mohs, and type B is gamma alumina with cubic crystals with particle size under 0.1 μm , specific gravity of 3.6, and a hardness 8. Type A cuts faster, but type B gives a finer finish. At high temperatures, gamma alumina transforms to the alpha crystal. The aluminum oxide most frequently used for refractories is the beta alumina and hexagonal crystals heat-stabilized with sodium.

Activated alumina is partly dehydrated alumina trihydrate, which has a strong affinity for moisture or gases and is used for dehydrating organic solvents, and hydrated alumina is alumina trihydrate.

$Al_2O_3 \cdot 3H_2O$ is used as a catalyst carrier.

Activated alumina F-1 is a porous form of alumina, Al_2O_3 , used for drying gases or liquids and is also used as a catalyst for many chemical processes.

Alumina ceramics are the most widely used oxide-type ceramic, chiefly because Al_2O_3 is plentiful, relatively low in cost, and equal to or better than most oxides and mechanical properties. Density can be varied over a wide range, as purity—down to about 90% Al_2O_3 —to meet specific application requirements. Al_2O_3 ceramics are the hardest, strongest, and stiffest of the oxides. They are also outstanding in electrical resistivity and dielectric strength, are resistant to a wide variety of chemicals, and are unaffected by air, water vapor, and sulfurous atmospheres. However, with a melting point of only 2037°C, they are relatively low in refractoriness, and at 1371°C retain only about 10% of room-temperature strength. Besides wide use as electrical insulators and chemical and aerospace applications, the high hardness and close dimensional tolerance capability of alumina make this ceramic suitable for such abrasion-resistant parts as textile guides, pump plungers, chute linings, discharge orifices, dies, and bearings.

Alumina Al-200, which is used for high-frequency insulators, gives a molded product with the tensile strength of 172 MPa, compressive strength of 2000 MPa, and specific gravity of 3.36. The coefficient of thermal expansion is half that of steel and the hardness about that of sapphire. Alumina AD-995 is a dense vacuum-tight ceramic for high-temperature electronic use. It is 99.5% Al_2O_3 with

no SiO_2 . The hardness is Rockwell N 80, and dielectric constant is 9.27. The maximum working temperature is 1760°C , and at 1093°C , it has a flexural strength of 200 MPa.

Other alumina products have found their way in the casting of hollow jet engine cores. These cores are then incorporated in molds into which eutectic superalloys are poured to form the turbine blades.

Alumina balls are available in sizes from 0.6 to 1.9 cm for reactor and catalytic beds. They are usually 99% alumina, with high resistance to heat and chemicals. Alumina fibers in the form of short linear crystals, called sapphire whiskers, have high strength up to 1375 MPa for use as a filler in plastics to increase heat resistance and dielectric properties. Continuous single-crystal sapphire (alumina filaments) has unusual physical properties: high tensile strength (over 2069 MPa) and modulus of elasticity of 448.2–482.7 GPa. The filaments are especially needed for use in metal composites at elevated temperatures and in highly corrosive environments. An unusual method for producing single-crystal fibers in lieu of a crystal-growing machine is the floating zone fiber-drawing process. The fibers are produced directly from a molten ceramic without using a crucible.

FP, a polycrystalline alumina (Al_2O_3) fiber, has been developed. The material has greater than 99% purity, and a melting point of 2045°C , which makes it attractive for use with high-temperature metal-matrix composite processing techniques. Thanks to a mechanism, currently not explainable by the developer of FP fibers (DuPont), a silica coating results in an increase in the tensile strength of the filaments to 1896 MPa even though the coating is approximately $0.25\text{ }\mu\text{m}$ thick and the modulus does not change. Fiber FP has been demonstrated as a reinforcement for magnesium, aluminum, lead, copper, and zinc, with emphasis to date on aluminum and magnesium materials.

Fumed alumina powder of submicrometer size is made by flame reduction of aluminum chloride. It is used in coatings and for plastics reinforcement and in the production of ferrite ceramic magnets.

Aluminum oxide film, or alumina film, used as a supporting material in ionizing tubes, is a strong, transparent sheet made by oxidizing aluminum foil, rubbing off the oxide on one side, and dissolving the foil in an acid solution to leave the oxide film on the other side. It is transparent to electrons. Alumina bubble brick is a lightweight refractory brick for kiln lining, made by passing molten alumina in front of an air jet, producing small hollow bubbles, which are then pressed into bricks and shapes.

The foam has a density of 448.5 kg/m^3 and porosity of 85%. The thermal conductivity at 1093°C is $0.002\text{ W/(cm}^2)(^\circ\text{C})$.

Aluminides

True metals include the alkali and alkaline earth metals, beryllium, magnesium, copper, silver, gold, and the transition elements. These metals exhibit those characteristics generally associated with the metallic state.

The B subgroups comprise the remaining metallic elements. These elements exhibit complex structures and significant departures from typically metallic properties. Aluminum, although considered under the B subgroup metals, is somewhat anomalous in that it exhibits many characteristics of a true metal.

The alloys of a true metal and a B subgroup element are very complex because their components differ electrochemically. This difference gives rise to a stronger tendency toward definite chemical combination of solid solution. Discreet geometrically ordered structures usually result. Such alloys are also termed “electron compounds.” The aluminides are phases in such alloys or compounds. A substantial number of beta, gamma, and epsilon phases have been observed in electron compounds, but few have been isolated and evaluated.

The development of intermetallic alloys into useful and practical structural materials remains, despite recent successes, a major scientific and engineering challenge. As with many new and advanced materials, hope and the promise of major breakthroughs in the near future have kept a very active and resilient fraction of the metallurgical community focused on intermetallic alloys.

Compared to conventional aerospace materials, aluminides of titanium, nickel, iron, niobium, etc., with various compositions offer attractive properties for potential structural applications. The combination of good high-temperature strength and creep capability, improved high-temperature environmental resistance, and relatively low density makes this general class of materials good candidates to replace more conventional titanium alloys and, in some instances, nickel-base superalloys. Moreover, titanium aluminide matrix composites appear to have the potential to surpass the monolithic titanium aluminides in a number of important property areas, and fabrication into composites form may be a partial solution to some of the current shortcomings attributed to monolithic titanium aluminides.

The material classes include monolithic and continuous fiber composite materials based on the intermetallic compositions Ti_3Al (α_2 -phase) and monolithic alloys based on the intermetallic composition TiAl (γ -phase). In their monolithic form, and as a matrix material for continuous fiber composites, titanium aluminides are important candidates to fill a need in the intermediate-temperature regime of 600°C – 1000°C . Before these materials can become flight-worthy, however, they must demonstrate reliable mechanical behavior over the range of anticipated surface conditions.

The β and γ phases that are found to exist in the Mo–Al alloy are generally considered to correspond to the compositions MoAl_3 and MoAl_2 , respectively.

Powder metallurgy techniques have proved feasible for the production of alloys of molybdenum and aluminum, provided care is taken to employ raw materials of high purity (99%+). As the temperature of the compact is raised, a strong exothermic reaction occurs at about 640°C causing a rapid rise in temperature to above 960°C in a matter of seconds. Bloating occurs, transforming the compact into a porous mass. Complete alloying, however, is accomplished. This porous, friable mass can be subsequently finally comminuted, repressed, and sintered (or hot pressed) to form a useful body with quite uniform in composition. Vacuum sintering at 1300°C for 1 h at $0.04\text{ }\mu\text{m}$ produces clean, oxide-free metal throughout. Wet comminution prevents caking of the powder, and a pyrophoric powder can be produced by prolonged milling.

Hot pressing is a highly successful means of forming bodies of molybdenum and aluminum previously reacted as mentioned earlier. Graphite dies are employed to which resistance heating techniques are applicable. A parting compound is required since aluminum is highly reactive with carbon causing sticking to the die walls.

Hot-pressed small bars exhibit modulus of rupture strengths ranging from 40,000 to 50,000 psi at room temperature, decreasing to 38,000 to 40,000 psi at 1040°C . Room temperature resistant to fuming nitric acid is excellent.

As has been recognized for some time, ordered intermetallic compounds have a number of properties that make them intrinsically more appealing than other metallic systems for high-temperature use. The primary requirements for high-temperature structural intermetallics, as with any high-temperature structural material, are that they (1) have a high melting point, (2) possess some degree of resistance to environmental degradation, (3) maintain structural and chemical stability at high temperatures, and (4) retain high specific mechanical properties at elevated temperatures whether they are intended as monolithic components or as reinforcing fibers or matrix in composite structures.

FIGURE A.2 Melting points of various intermetallic compounds relative to superalloys. (From Schwartz, M., *Emerging Technology*, Technomic Publishing Co., Lancaster, PA, 1996. With permission.)

Melting point is a useful first approximation of the high-temperature performance of a material, as various high-temperature mechanical properties (e.g., strengthen creep resistance) are limited by thermally assisted or diffusional processes and thus tend to scale with a melting point of the material. Therefore, the intermetallic can be crudely ranked in terms of their melting points to indicate their future applicability as high-temperature structural materials.

As may be seen in Figure A.2, metallic materials (intermetallics or otherwise) that are currently in use are being studied that melt at temperatures much lower than 1650°C. If these materials are discounted from consideration, the remaining intermetallics in Figure A.2 may be roughly divided into two groups; those that fall in the temperature range just above 1650°C and those whose melting points extend to much higher temperatures.

This second group of intermetallic compounds belongs to a group of intermetallics that are predicted on the basis of the Engel-Brewer phase stability theory.

There are several techniques that have been developed and used to improve the toughness of intermetallics as well as intermetallic compounds:

- Crystal structure modification (macroalloying)
- Microalloying
- Control of grain size or shape
- Reinforcement by ductile fibers or particles
- Control of substructure

Table A.10 includes the aforementioned major categories; however, the use of hydrostatic pressure and suppression of environment should also be cited.

Additions of chromium and manganese have induced appreciable compressive ductility and modest improvements in bend ductility of Al₃Ti, but significant tensile ductility remains unattainable.

The interest in aluminides has covered the high-melting-point phases in metallic systems with aluminum.

Ordered intermetallics constitute a unique class of metallic materials that form long-range-ordered crystal structures (Figure A.3) below a critical temperature that is generally referred to as the critical ordering temperature (T_c). These intermetallics usually exist in relatively narrow compositional ranges around simple stoichiometric ratios.

The search for new high-temperature structural materials has stimulated much interest in ordered intermetallics. Recent interest has been focused on aluminides of nickel, iron, and titanium. These aluminides possess many attributes that make them attractive for high-temperature structural applications. They contain enough aluminum to form, in oxidizing environments, thin films of aluminide oxides that often are compact and protective. They have low densities, relatively high melting points, and good high-temperature strength properties. For example, Ni₃Al shows an increase rather than a decrease in yield strength with increasing temperatures. The aluminides of interest are described in Table A.11.

In the range of 14%–34%, aluminum by weight occurs in two intermetallic phases, Ni₃Al and NiAl. The alloys are prepared by powder metallurgy and by casting techniques. Compacts of NiAl + 5% Ni, produced by powder techniques, exhibit room-temperature modulus of rupture values of 144,000 psi, and heat shock resistance is considered excellent. They have good resistance to red and white fuming nitric acids.

The cast alloys of nickel and aluminum exhibit an increasing exothermic character with increasing aluminum content. Alloys with the exception of the 34% aluminum alloy and NiAl (31.5% Al) produce sound castings free of excessive porosity. A room-temperature tensile strength of approximately 49,000 psi is exhibited by the Ni_3Al compound with about 5% elongation. The 25% Al (NiAl) alloy has a room temperature tensile strength of 24,000 psi.

The 17.5% aluminum alloy that contained a mixture of the phases Ni_3Al and NiAl exhibits the best strength properties. Room-temperature tensile strength is approximately 80,000 psi with about 2% elongation, while at 815°C, the tensile strength is about 50,000 psi. This alloy can be rolled at 1315°C and possesses good thermal shock and oxidation resistance. Impact resistance is fair. The 100 h stress-to-rupture strength at 734°C is 14,000 psi, but it should be noted creep rates are high.

Ni_3Al is an intermetallic phase that forms at the nickel-rich end of the Ni–Al system and has a crystal structure (Figure A.3). Ni_3Al is the most important strengthening constituent of nickel-base superalloys. This is because the aluminide possesses an excellent elevated-temperature strength in addition to good oxidation resistance. Unlike conventional materials, Ni_3Al and its alloy show a yield anomaly, that is, its yield strength increases rather than decreases with increasing temperature.

Boron has been found to be most effective in improving the tensile ductility of Ni_3Al (<25% aluminum) tested in air at room temperature. Other tests indicated foreign-doped Ni_3Al is not sensitive to test environment at room temperature.

Boron-free Ni_3Al (24% Al) has shown a ductility of only 8.2% in dry O_2 while boron-doped Ni_3Al exhibited 42.8%. This suggests that boron segregation also enhances the grain-boundary cohesion in Ni_3Al . In addition to boron, iron, chromium, and zirconium appear to enhance the grain-boundary properties and improve the tensile ductility of Ni_3Al at room temperature.

The mechanical properties of Ni_3Al strongly depend on deviation from alloy's stoichiometry (i.e., aluminum/nickel ratio) and ternary alloying additions. The aluminide is capable of dissolving substantial alloying additions without forming second phases; as a result, its deformation and fracture behavior can be strongly altered by alloying.

Mechanical and metallurgical properties of Ni_3Al can be improved by alloying additions. Recent alloy design efforts have led to the development of Ni_3Al -base alloys with the following composition range (in atomic percent) for structural use at elevated temperatures in hostile environments: Ni–(14%–18%) Al–(6%–9%) Cr–(1%–4%) Mo–(0.01%–1.5%) Zr/Hf–(0.01%–0.20%) B.

NiAl containing more than 41 at% forms a single-phase ordered B_2 structure based on the body centered cubic lattice (Figure A.3). In terms of thermophysical properties, B_2 NiAl offers more potential for high-temperature structural applications than L_1 NiAl . It has a higher melting point (1638°C), a substantially lower density (5.86 g/cm³), and a distinctly higher thermal conductivity 76 W/(m K), at ambient temperatures. In addition, NiAl has excellent oxidation resistance at high temperatures.

The structural use of NiAl suffers from two major drawbacks: poor fracture resistance at ambient temperatures and low strength and creep resistance at elevated temperatures. Single crystals of NiAl are quite ductile and compression, but both single-crystal and polycrystalline NiAl appear to be brittle in tension at ambient temperatures.

Because of the potential use of NiAl at high temperatures, considerable effort has been devoted to understanding brittle fracture and improving mechanical properties of NiAl during the past years.

The room-temperature tensile ductility of NiAl is as high as 6% by adding about 0.2% at% iron. The ductility decreases sharply when the iron content is beyond 0.4 at%. A similar effect has been observed for molybdenum and gallium.

Gamma alloys may be processed by

- Casting
- Ingot metallurgy (IM)
- Powder metallurgy
- Sheet forming

The XD™ process for producing gamma alloys containing TiB_{2p} can be classified separately, although the XD alloys are produced by either the casting process or the IM process. Each process can involve one or more routes.

The conventional method of producing foils from brittle materials was chemical milling. The approach involves suspending hot-rolled and surface-ground 0.050 mm thick plates of the material in

A

a pickling bath and dissolving the metal until the plates are about 0.015 mm thick. For γ -TiAl, the chemical milling technique yields a poor surface finish on the foil.

Engineers knew that the γ -TiAl, while brittle in tension, accepts high compression strain without failing. So they designed a new "isobaric" rolling mill to maintain triaxial compression on the material as it passes through the rolls. This proprietary process increases yield from the original ingot to around 50% and provides thinner (0.03–0.05 mm) foils with smaller grains. As a result, isobaric cold rolling is a breakthrough technology. A cold-rolled and annealed γ -Ti-48-2-2 strip has a hardness of 260 H_v (Vickers).

Other processing methods include the self-propagating high-temperature synthesis (SHS) process, which starts with a structure of alternating layers of pure metal sheets or foils (e.g., iron, nickel, or titanium) and aluminum sheets or foils. The ductile metal layers are formed into the desired shape, either before or during the SHS reaction. The SHS reaction is initiated by heating in a vacuum. When the system reaches the initiation temperature (typically less than 660°C, the melting point of aluminum) an SHS reaction begins at the metal interface, that is, between the aluminum and the iron, nickel, or titanium metals. The heat generated from the reaction melts the aluminum allowing rapid reaction with the adjacent metal layers. That is, the SHS reaction occurs between the elemental metals producing well-bonded layers of unreacted elemental metal and metal–aluminum intermetallics. In this technique, the aluminum completely reacts, forming a titanium–aluminide–titanium, a nickel–aluminide–nickel, or an iron–aluminide–iron layered composite structure.

A second technique takes elemental metal powder mixtures that are placed between layers of an elemental metal foil worksheet, after which the entire layout is heated under pressure in a vacuum. Starting powders have been iron, nickel, or titanium mixed with aluminum. Starting elemental metal sheets have been titanium, nickel, or iron.

IM Developments

A mixture of titanium and 34 wt.% aluminum, that is, 48 at%, was prepared by blending commercially available elemental powders with a maximum grain size of 100 μ m compacted at room temperature in a uniaxial pressing machine to billets of 50 mm in diameter.

Titanium aluminide foils were produced using a combination of a standard Powder metallurgy (P/M) technique (extrusion), aluminum technology (rolling), and advanced titanium technology (Superplastic forming device). Claims have been made that since these techniques were available on a large scale, it should be possible to produce titanium aluminide foils in production.

A series of low-pressure turbine blades fabricated from titanium aluminide was successfully tested and this development could eventually result in reducing the weight of aviation gas turbines by hundreds of pounds. Blades of 49% Ti–47% Al–2% Cr–2% Nb, which have about half the weight of comparable components made from conventional nickel-base alloys, were run in the fifth low-pressure turbine stage of a CF6-80C2 power plant, and during the tests, the blades went through 1000 flight cycles. Compared with traditional nickel-base alloys, the material has half the density and is comparable in strength up to about 700°C. The titanium aluminide also is about 50% stiffer than conventional titanium alloys. If used in the low-pressure section of new aircraft engines as blade material, the titanium aluminide could cut engine weight by more than 136.01 kg.

The 98 plates used in the tests weighed 217 g. Comparable nickel alloy components weigh 383 g. In an ideal situation, the lighter blades would also allow turbine wheels to be lighter and less robust because the reduced-weight blades create lower stresses during operation.

The titanium aluminide alloys used to fabricate the blades were solid airfoils and were cast using conventional foundry techniques.

New titanium aluminum alloys, stronger and tougher than conventional α_2 (Ti₃Al) materials, are based on the ordered orthorhombic-phase Ti₃AlNb (Ti–25 at% Al–25 at% Nb).

The materials are potential weight-saving alternatives to nickel-base superalloys and relatively low temperature (650°C) aircraft gas-turbine engine applications. Several examples include exhaust-nozzle structures, compressor casings, and various compressor components; while the density of Ti₃AlNb-base alloys (and other titanium aluminides) is less than two-thirds that of nickel-base superalloys, such as alloy 718, the lower weight can be translated into higher thrust-to-weight ratios or gains in fuel efficiency.

Of two new alloys, the Ti–22% Al–27% Nb has the best combination of high-temperature strength and room-temperature ductility and fracture toughness. The alloy is much stronger than conventional α_2 titanium aluminides such as Ti–24% Al–11% Nb and Ti–25% Al–10% Nb–3% V–1% Mo. It also has a higher strength-to-weight ratio, even though it is slightly denser. For example, Ti–22% Al–27% Nb as a factor-of-two advantage in strength-to-weight ratio over Ti–25% Al–10% Nb–3% V–1% Mo, an α_2 -alloy, from room temperature to 650°C. Fracture toughness (K_{Ic}) of Ti–22% Al–27% Nb averages about 28 MPa m^{1/2}, which is higher than those of the α_2 -alloys Ti–25% Al–10% Nb–3% V–1% Mo (K_{Ic} = 14 MPa m^{1/2}) and Ti–24% Al–17% Nb–1% Mo (19 MPa m^{1/2}). Creep behavior of the Ti₃AlNb-base alloy is competitive with lower toughness titanium aluminides that have been optimized for creep resistance.

Applications

Coatings

NiAl is the basis of a family of oxidation- and corrosion-resistant coatings that have been used on nickel-base and cobalt-base superalloys over the past 40 years. NiAl coatings 25–100 μ m thick are typically applied by a pack cementation process.

Both inward diffusion and outward diffusion coatings have been applied. The mechanisms of coating degradation include a depletion due to spallation and reaction with the substrate. A variety of alloying additions, most notably chromium and yttrium, have been applied to improve performance and thermal cycling and hot corrosion.

Turbine Blades and Vanes

The advantages associated with NiAl as a candidate structural material in advanced gas turbine engines include a 30% reduction in density over current nickel-base superalloys, good intrinsic environmental resistance, a thermal conductivity three to eight times larger than nickel-base superalloys (for improved cooling efficiency), and a melting temperature that is approximately 128°C higher than superalloys (for higher operating temperatures).

The processing, fabrication, and engineering design of NiAl, along with an understanding and improvement in impact properties, will also provide significant technical challenges that must be overcome before NiAl can be successfully employed as a structural material that may compete with current nickel-base superalloys. It is important to point out that a single-crystal approach is crucial to obtaining a balance of both room-temperature ductility and high-temperature strength. Although NiAl-base composites may provide an alternative avenue to balanced properties, this approach is still in its infancy.

Electronic Applications

NiAl is an attractive material for metallization on III–V semiconductors and is also a critical component in complex metal/III–V

semiconductor heterostructures, such as enhanced-barrier Schottky contacts and semiconductor-clad metallic quantum wells. The characteristics that make NiAl an attractive candidate include a good lattice parameter match with several semiconductors (for epitaxy), chemical stability, good electrical conductivity, and a stable native oxide that allows patterning in air without destroying electrical continuity. An NiAl layer 3.3 mm thick is currently the thinnest independently contacted electrode in any solid-state device.

High-Temperature Applications

Among the alloys currently being considered as replacements for superalloys in high-temperature applications, some of the most promising are the intermetallic compounds in the Nb–Al system. The three compounds NbAl₃, NbAl₂, and Nb₃Al have melting temperatures in excess of many candidate replacement materials and densities that are superior to or competitive with those materials. Furthermore, the crystal structures, although complex, are reasonably well understood. In addition to these physical properties, there is a distinct processing consideration that leads to a heightened interest in this system. The compounds of the Nb–Al system represent the highest melting temperature alloys that can be processed using currently active superalloy techniques, that is, the various vacuum and hearth melting techniques.

The intermetallic compounds of the Nb–Al system, when systematically viewed as a whole, demonstrate both an orderly progression of high-temperature properties and a great deal of promise for future applications. Vickers microhardness as a function of temperature proceeds from NbAl₃, which is inferior to Ni₃Al, to Nb₃Al, which is the highest-melting-temperature compound with a temperature superiority of about 600°C over Ni₃Al.

Iron aluminides based on Fe₃Al and FeAl (Figure A.3) have excellent oxidation and corrosion resistance because they are capable of forming protective oxide scales at elevated temperatures in hostile environments. These aluminides exhibit corrosion rates lower than those of promising iron-based alloys (including coating material) by a couple orders of magnitude when tested in a severe sulfidizing environment at 800°C. The major drawbacks of the aluminides are their poor ductility and brittle fracture at ambient temperatures and poor strength and creep resistance above 600°C.

Iron aluminides have been known to be brittle at room temperature for more than 60 years; however, the major cause of their low ductility and brittle fracture was not identified until recently. A study of the environmental effects on tensile properties indicates that the poor ductility commonly observed in air test is caused mainly by an extrinsic effect—environmental embrittlement.

The understanding of the cause of brittleness and iron aluminides has led to new directions in the design of ductile iron aluminide alloys. The schemes used to improve the ductility of Fe₃Al–FeAl alloys include control of surface conditions, reduction of hydrogen solubility and diffusion by alloying additions, refinement of grain structure by thermomechanical treatment, enhancement of grain-boundary cohesion by microalloying, and control of grain shape and recrystallization condition. The ductile Fe₃Al alloys show a distinctly high yield strength and a high ductility of 13%–60% when tested in air at room temperature. Similarly, FeAl (35.8 at% Al) alloys show an increase in room-temperature ductility from 2% to 11% as a result of alloying additions (zirconium, molybdenum, and boron) and grain-structure refinement. This ductility further increased to 14% by formation of protective oxide scales on specimen surfaces through preoxidation at 700°C. The room-temperature ductility of Fe₃Al and FeAl can be significantly improved by refining grain structure via powder extrusion with or without second-phase particles (such as TiB₂). The strength of Fe₃Al and FeAl alloys

at elevated temperatures can be improved by alloying with molybdenum, zirconium, niobium, titanium, and TiB₂.

Gamma alloys of titanium aluminide can be grouped into single-phase (γ)-alloys and two-phase ($\alpha_2 + \gamma$)-alloys. Single-phase alloys attracted attention initially because of their excellent resistance to environmental attack (e.g., oxidation of hydrogen absorption). In spite of a lack of progress toward overcoming their poor ductility and fracture toughness, interest in these engineering alloys has not diminished. Gamma titanium aluminide alloys of importance are thus two-phase alloys based on Ti–(45%–49%)Al with appropriate combinations of alloying elements.

Aluminized Steel

Standard type I aluminized steel consists of a hot coating of 92% aluminum and 8% silicon on cold-rolled sheet steel for oxidation and corrosion resistance. The coating provides good oxidation resistance in continuous service to 1250°F (675°C) and is used for auto exhaust-system components and other applications. The thicker coating provides the better environmental resistance, but the thinner one is preferred for parts requiring severe forming because of its better adhesion. Type 2 aluminized steel provides still better environmental resistance but is limited to parts requiring still less severe forming.

Galvalume

A cold-rolled steel, having a thin hot-dip coating of 55% aluminum, 43.4% zinc, and 1.6% silicon on both sides, was developed by Bethlehem Steel as an alternative to type 2 aluminized steel. It is substantially stronger and correspondingly less ductile than the aluminized steel, scale resistant to 1250°F (675°C), and superior to conventional galvanized steel and corrosion resistance and rural, industrial, and marine atmospheres. Applications include roofing for pre engineered buildings, auto exhaust-system parts, agricultural equipment, and appliance parts.

Aluminizing

Any treatment that causes aluminum to diffuse into the surface of a component (usually steel) to improve corrosion resistance, particularly resistance to oxidation at temperatures up to about 900°C. Processes include dipping in molten metal, metal spraying followed by a diffusion heat treatment, or exposure of the steel at elevated temperature to a gaseous or liquid environment capable of releasing aluminum into the metal surface. The common feature is that the diffusion and the formation of an intermetallic alloy layer ensures good adhesion in contrast to metal spraying, which merely applies a mechanically adherent coating.

Aluminothermic Welding

Same as thermite welding.

Aluminum

Called aluminium in England, aluminum is a white metal with a bluish tinge (symbol Al, atomic weight 26.97), obtained chiefly from bauxite. It is the most widely distributed of the elements next to O₂ and silicon, occurring in all common clays. Aluminum metal is produced by first extracting alumina (aluminum oxide) from the bauxite

A

by a chemical process. The alumina is then dissolved in a molten electrolyte, and an electric current is passed through it, causing the metallic aluminum to be deposited on the cathode. The metal was discovered in 1727 but was obtained only in small amounts until it was reduced electrolytically in 1885.

Pure (99.99%) aluminum has a specific gravity of 2.70 or a density of 2685 kg/m³, a melting point of 660°C, electrical and thermal conductivities about two-thirds that of copper, and a tensile modulus of elasticity of 62,000 MPa. The metal is nonmagnetic, highly reflective, and has a face-centered cubic crystal structure. Soft and ductile in the annealed condition, it is readily cold worked to moderate strength. It resists corrosion in many environments as a result of the presence of a thin aluminum oxide film.

Iron, silicon, and copper are the principal impurities in commercially pure aluminum, wrought products containing at least 99% alumina and a foil product containing at least 99.99%. Such unalloyed aluminum is available in a wide variety of mill forms and constitutes the aluminum 1XXX series in the designation system for wrought aluminum and aluminum alloys. Annealed sheet is quite ductile—35%–45% tensile elongation—but weak, having a tensile yield strength of 27–35 MPa. Cold reduction of 75% increases yield strength to 124–166 MPa. Thus, the unalloyed metal is used far more for its electrical, thermal, corrosion-resistant, and cosmetic characteristics than for its mechanical properties. Applications include electrical and thermal conductors, capacitor electrodes, heat exchangers, chemical equipment, packaging foil, heat and light reflectors, and decorative trim.

Aluminum flake enhances the reflectance and durability of paints. Aluminum powder is used for powder-metal parts. Aluminum and alumina paste are used in catalysts, soaps, explosives, fuels, and thermite welding. Aluminum shot is used to deoxidize steel, and aluminum foam, made by foaming the metal with zirconium hydride or other hydrides, is an effective core material for lightweight structures.

Anodized aluminum is aluminum with a hard aluminum oxide surface imparted electrolytically using the metal as the anode. The coating, which is much thicker than the naturally formed aluminum oxide film, provides additional corrosion and weathering resistance in certain environments but is generally no more protective in acidic or alkaline solutions outside the 4–8.5 pH range. The coating is nonconductive, wear resistant, and can be produced in various colors, thus enhancing decorative appeal. Whereas the naturally formed oxide film is less than a millionth of an inch thick, anodized coatings range from 0.005 to 0.008 mm for bright auto trim to as much as 0.030 mm for architectural applications.

Aluminum Alloys

Alloying aluminum with various elements markedly improves mechanical properties, strength primarily, at only a slight sacrifice in density, thus increasing specific strength, or strength-to-weight ratio. Traditionally, wrought alloys have been produced by thermomechanically processing cast ingot into mill products such as billet, bar, plate, sheet, extrusions, and wire. For some alloys, however, such mill products are now made by similarly processing “ingot” consolidated from powder. Such alloys are called powder metal (PM) wrought alloys or simply PM alloys. To distinguish the traditional type from these, they are now sometimes referred to as ingot-metallurgy (IM) alloys or ingot-cast alloys. Another class of PM alloys is used to make PM parts by pressing and sintering the powder to near-net shape. There are also many cast alloys. All told, there are about 100 commercial aluminum alloys.

There are two principal kinds of wrought alloys: (1) heat-treatable alloys—those strengthened primarily by solution heat treatment or solution heat treatment and artificial aging (precipitation hardening)—and (2) non-heat-treatable alloys—those that depend primarily on cold work for strengthening. Alloy designations are a continuation of the four-digit system noted for aluminum, followed with a letter to designate the temper or condition of the alloy: F (as-fabricated condition), O (annealed), H (strain hardened), W (solution heat treated and unstable, that is, the alloy is prone to natural aging in air at room temperature), and T (heat treated to a stable condition). Numerals following T and H designations further distinguish between tempers or conditions. T3, for example, refers to alloys that have been solution heat treated, cold worked, and naturally aged to a substantially stable condition. T6 denotes alloys that have been solution heat treated and artificially aged. H designations are followed by two or three digits. The first (1, 2, or 3) indicates a specific sequence of operations applied. The second (1–8) refers to the degree of strain hardening (the higher the number, the greater the amount of strain or hardening; 8 corresponds to the amount induced by a cold reduction of about 75%). The third (1–9) further distinguishes between middle treatments (Table A.12).

The aluminum alloy 2XXX series is characterized by copper (2.3%–6.3%) as the principal alloying element. Most of these alloys also contain lesser amounts of magnesium and manganese, and some may contain small amounts of other ingredients, such as iron, nickel, titanium, vanadium, zinc, and zirconium. The 2XXX alloys are strengthened mainly by solution heat treatment, sometimes by solution heat treatment and artificial aging. Among the more common, especially for structural aircraft applications, are aluminum alloys 2014, 2024, and 2219, which can be heat treated to tensile yield strengths in the range of 276–414 MPa. A recently developed alloy for auto body panels is aluminum alloy 2036, which in the T4 temper provides a tensile yield strength of about 195 MPa. Aluminum alloy 2XXX series is not as corrosion resistant as other aluminum alloys and thus is often clad with a thin layer of essentially pure aluminum or a more corrosion-resistant aluminum alloy, especially for aircraft applications.

Manganese (0.5%–1.2%) is a distinguishing alloying element in the aluminum alloy 3XXX series. Aluminum alloy 3003 also contains 0.12% copper. Aluminum alloys 3004 and 3105 also contain 1% and 0.5% magnesium, respectively. Strengthened by strain hardening, 3XXX alloys provide maximum tensile yield strengths in the range of 186–248 MPa and are used for chemical equipment, storage tanks, cooking utensils, furniture, builders’ hardware, and residential siding.

The aluminum alloy 4XXX series is characterized by the addition of silicon: about 12%, for example, an aluminum alloy 4032 and 5% aluminum alloy 4043. Aluminum alloy 4032, which also contains 1% magnesium and almost as much copper and nickel, is heat treatable, providing a tensile yield strength of about 315 MPa in the T6 temper. This, combined with its high wear resistance and low thermal expansivity, has made it popular for forged engine pistons. Aluminum alloy 4043, which is alloyed only with silicon, is a strain-hardenable alloy used for welding rod and wire. Some Al–Si alloys are also used for brazing, others for architectural applications. Their appeal for architectural use stems from the dark-gray color they develop and anodizing.

The principal alloying element in the aluminum alloy 5XXX series is magnesium, which may range from about 1% to 5%, and is often combined with lesser amounts of manganese and/or chromium. Like 3XXX alloys, the 5XXX are hardenable only by strain hardening, and all are available in a wide variety of H tempers.

TABLE A.12
Aluminum Wrought Alloys

Designation	1100		2011		2014		2024		2036	2219		3003

Tensile yield strength range from less than 69 MPa in the annealed condition to more than 276 MPa in highly strained conditions. Aluminum alloys 5083, 5154, 5454, and 5456 are widely used for welded structures, pressure vessels, and storage tanks, others for more general applications, such as appliances, cooking utensils, builders' hardware, residential siding, auto panels and trim, cable sheathing, and hydraulic tubing.

The aluminum alloy 6XXX series is characterized by modest additions (0.4%–1.4%) of silicon and magnesium and can be strengthened by heat treatment. Except for auto sheet aluminum alloys 6009 and 6010, which are typically supplied and used in the T4 temper, the alloys are strengthened by solution heat treatment and artificial aging. As a class, these alloys are intermediate in strength to aluminum alloy 2XXX and aluminum alloy 7XXX but provide good overall fabricability. The auto sheet alloys are relatively new. More traditional among the dozen or so alloys of this kind are aluminum alloy 6061, which is used for truck, marine, and railroad-car structures, pipelines, and furniture, and aluminum alloy 6063 furniture, railings, and architectural applications. Other applications include complex forgings, high-strength conductors, and screw-machine products.

Zinc is the major alloying element in the aluminum alloy 7XXX series, and it is usually combined with magnesium for strengthening by heat treatment. An exception is aluminum alloy 7072, which is

alloyed only with 1% zinc, is hardenable by strain hardening and is used for fin stock or as a clad for other aluminum alloys. The other alloys, such as aluminum alloy 7005, 7049, 7050, 7072, 7075, 7175, 7178, and 7475, contain 4.5%–7.6% Zn, 1.4%–2.7% Mg, and, in some cases, also include copper, magnesium, silicon, titanium, or zirconium. These heat-treatable alloys are the strongest of aluminum alloys, with tensile yield strengths of some exceeding 483 MPa in the T6 temper. They are widely used for high-strength structures, primarily in aircraft.

Cast Aluminum Alloys

Of some 40 or so standard casting alloys, 10 are aluminum die-casting alloys. The others are aluminum sand-casting alloys and/or aluminum permanent-mold-casting alloys. Some of the latter also are used for plaster-mold casting, investment casting, and centrifugal casting. Although the die-casting alloys are not normally heat treated, those for sand and/or permanent-mold casting often are, usually by solution heat treatment and artificial aging. Both heat-treatable and non-heat-treatable alloys are available. The heat-treatable alloys, which can be solution heat treated and aged similar to wrought heat-treatable grades, carry the temper designations T2, T4, T5, T6, or T7. Die castings are seldom solution heat-treated because of the danger of blistering.

A

The major alloying addition of several important casting alloys is silicon, which improves the castability of aluminum and provides moderate strength. Other elements are added primarily to increase the tensile strength. Most die castings are made of alloy 413.0 or 380.0. Alloy 443.0 has been very popular in architectural work, and 355.0 and 356.0 are the principal alloys for sand casting. Number 390.0 is employed for die-cast automotive engine cylinder blocks, and alloy F332.0 is used for pistons for internal combustion engines.

Casting alloys are significant users of secondary metal (recovered from scrap for reuse). Thus, casting alloys usually contain minor amounts of a variety of elements; these do no harm as long as they are kept within certain limits. The use of secondary metal is also increasing importance in wrought alloy manufacturing as producers take steps to reduce the energy that is required in producing fabricated aluminum products.

Aluminum alloy 380.0 and its modifications constitute the bulk of die-casting applications. Containing 8.5% Si, 3.5% Cu, and as much as 2% Fe, it provides a tensile yield strength of about 165 MPa, good corrosion resistance, and is quite fluid and free from hot shortness, and thus is relatively castable. Engine cylinder heads, typewriter frames, and various housings are among its applications. Aluminum alloy 390.0, a high-silicon (17%) Cu–Mg–Zn alloy, is the strongest of the die-casting alloys, providing a tensile yield strength of about 240 MPa as cast and 260 MPa in the T5 temper. Like high silicon in wrought alloys, it also features low thermal expansivity and excellent wear resistance. Typical applications include auto engine cylinder blocks, breakthroughs, compressors, and pumps requiring abrasion resistance. Aluminum alloys 383.0, 384.0, 413.0, and A413.0 provide the best die-filling capacity and have excellent resistance to hot cracking and die sticking. Aluminum alloy 518.0 provides the best corrosion resistance, machinability, and polishability but is more susceptible to hot cracking and die sticking than the other alloys.

Sand and/or permanent-mold casting alloys are encompassed in each of the aluminum alloy 2XX.X–8XX.X series. As-cast,

tensile yield strengths range from about 97 MPa for 208.0–200 MPa or aluminum alloy A 390.0. In various solution-treated and aged conditions, several alloys can provide tensile yield strengths exceeding 280 MPa. Strongest of the alloys—415 MPa in the T7 temper and 435 MPa in the T6—is aluminum alloy 201.0, which contains 0.7% Ag and 0.25% Ti in addition to 4.6% Cu and small amounts of magnesium and manganese. The T7 temper is suggested for applications requiring stress-corrosion resistance. Applications for 201.0 include aircraft and ordinance fittings and housings, engine cylinder heads, and pistons, pumps, and impellers. Other more commonly used high-strength alloys are aluminum alloys 354.0, 355.0, and 356.0, which are alloyed primarily with silicon, copper, magnesium, manganese, iron, and zinc, and which are used for auto and aircraft components. Premium-quality aluminum alloy castings are those guaranteed to meet minimum tensile properties throughout the casting or in specifically designated areas.

Aluminum–Lithium Alloys

Aluminum–lithium (Al–Li) alloys are a significant recent development in high-strength wrought aluminum alloys. Lithium is the lightest metal in existence. For each weight percent of lithium added to aluminum, there is a corresponding decrease of 3% in the weight of the alloy. Therefore, Al–Li alloys are for the attractive property of low density. Because of the very low density of lithium, every 1% of this alkali metal can provide a 3% reduction in density and a 10% increase in stiffness-to-density ratio relative to conventional 2XXX and 7XXX alloys. Thus, these alloys, such as aluminum alloys 2090 and 2091 (there are several others, including proprietary ones), are extremely promising for future aircraft applications, see Table A.13. These alloys are comparable in strength with some of the strongest traditional alloys. Some are ingot-cast products, others PM-wrought alloys.

TABLE A.13
Aluminum–Lithium Alloys

Product Form	Alloy	Temper of End Use Condition and Definition	Property Category
Sheet	AA8090	T81—solution treated, quenched, stretched, and precipitation heat treated to an underaged condition	Damage tolerant: low strength but enhanced toughness and impact resistance.
	AA8090	T621—resolution treated by the user, quenched, and precipitation heat treated to an underaged condition (same aging time and temperature as for T81)	Resolution treatment by the user to promote enhanced formability.
	AA8090	T8—solution treated, quenched, stretched, and precipitation heat treated to a near-peak aged condition	Medium strength where some reduction in toughness and impact resistance compared to T81 and T621 can be tolerated.
Extruded sections (solid and hollow)	AA8090	T8511—solution treated, quenched, controlled stretched, and precipitation heat treated to a near-peak aged condition	Medium/high strength.
Die forgings	AA8090	T852—solution treated, quenched, cold compressed, and precipitation heat treated to a near-peak aged condition	Medium/high strength.
	AA5091	H112—as forged	Medium/high strength but where cold compression is impractical or insufficient to achieve properties if made from AA8090.

Source: *Adv. Mater. Proc.*, 41–43, October 1992. With permission.

A second beneficial effect of lithium additions is the increase in elastic modulus (stiffness). Also, as the amount of lithium is increased, there is a corresponding increase in strength due to the presence of very small precipitates that act as strengthening agents to the aluminum. As the precipitates grow during heat treatment, the strength increases to a limit, then begins to decrease. Al–Li alloys therefore come under the classification of precipitation-strengthening alloys.

With the exception of the PM alloy AA 5091, all the current commercially available Al–Li alloys are produced by direct-chill casting and require a precipitation-aging heat treatment to achieve the required properties. In Al–Li alloys containing greater than 1.3% (by weight) of lithium, the intermetallic phase $\delta\text{-Al}_3\text{Li}$ precipitates upon natural or artificial aging, but the associated strengthening effect is insufficient to meet the medium or high strength levels usually required (the damage tolerant temper in AA 8090 is an exception).

Cold-working operation is a prime requirement for IM alloys containing relatively high levels of lithium, such as AA 8090 or AA 2090, if optimum medium-strength or high-strength properties are to be achieved. Cold working is readily applied to sheet, plate, and extrusions by stretching, although it must be recognized that in most cases, this can only be carried out by the metal manufacturer.

Alloy AA 5091 is made by the PM process of mechanical alloying (MA). This technology avoids the limitations arising from the need to cold-compress alloys AA 8090 and AA 2090 as forgings, because it is dispersion strengthened during manufacture. Through careful selection of the Al–Li–Mg base composition, a single-phase solid solution is achieved, and the need for heat treatment is eliminated.

The MA process is inherently more expensive than direct-chill casting and is not a practical route for producing large rectangular-section ingots for sheet or plate rolling. However, it is useful for certain parts in which the configuration of the forged components would not allow adequate cold compression to be achieved in alloys AA 8090 or AA 2090.

Powder Metallurgy Alloys

Elements such as iron, cobalt, and nickel have been added to aluminum in large quantities to produce alloys that have relatively stable structures at elevated temperatures and higher elastic moduli than conventional aluminum alloys.

The PM process is a rapid solidification process that involves the transformation of finely divided liquid either in the form of droplets or thin sheets that become solid at high solidification rates (on the order of 10^4 K/s). Solidification occurs as heat is removed from the molten metal.

Rapid-solidification-process aluminum alloys containing iron and cerium appear to result in alloys that have refined particle-size distribution and improved high-temperature stability. These PM alloys appear competitive with titanium up to 191°C.

Aluminum PM parts are made mainly from aluminum alloys 201 AB and 601 AB. Both are copper, silicon, and magnesium compositions that can be heat treated to the T4 or T6 tempers after sintering. The 201 AB is the stronger, having 324 MPa tensile yield strength for 95% dense material in the T6 temper as compared with about 241 MPa for 601 AB for these conditions.

Mechanical Alloying

This process circumvents the limitations of conventional ingot casting. Blends of powders are mixed in a ball mill. A drum is mounted horizontally and half filled with steel balls and blends of elemental

metal powders. As the drum rotates, the balls drop on the metal powder. The degree of homogeneity of the powder mixture is determined by the size of the particles in the mixture.

Aluminum–Beryllium Alloys (AlBeMet)

AlBeMetAE is an alloy of aluminum and beryllium. The Al–62Be alloy has the modulus of steel at 200 GPa and density of 2.1 g/cm³, approximately 20% that of steel, which gives a specific modulus of 950×10^6 cm.

Powder processing for AlBeMet is well established. First, inert-gas atomization produces prealloyed powder. The powder is cold isostatically pressed to a density of about 80% of theoretical, then consolidated by extrusion.

The alloy varies from 60% to 65% Be and 35% to 40% Al. The alloy is formed by melting spherical beryllium and aluminum powder and then is atomized, and the metals are mixed. As the metal mixture cools, an alloy with a matrix-like structure is formed. The resulting materials extruded and can be rolled or formed with hot isostatic pressing. AlBeMet also can be dip brazed or welded.

The extruded bar may be fabricated directly into parts, or cut for cross rolling into sheet. Sheet and plate thicknesses of 7.6 mm are produced by rolling, followed by grinding to final gauge. This sheet has essentially isotropic properties in the sheet plane.

A range of applications is made economically possible by the extrusion process, which has produced extrusions with diameters up to 25 cm. For example, profiled AlBeMet extrusions have been fabricated into computer hard disk drive arms, with over one million parts machined from extruded bar stock.

AlBeMet is also produced as hot isostatically pressed block. This is quite useful for prototype parts, and for components in which strength and ductility are of secondary importance to stiffness, density, modulus, thermal conductivity, and thermal expansion. The input powder for hot isostatic pressing is the same as that for wrought product manufacture. The processes carried out after degassing to remove adsorbed species such as water vapor.

The physical properties of AlBeMet are largely independent of processing route. However, they are critically dependent on the beryllium content of the alloy. Although AlBeMet 162 with 62 wt% Be is the most common composition, others can be quite useful. The most striking physical properties are modulus and density. The modulus is substantially higher, and the density is significantly lower than conventional materials such as Al–Li, which is typically 2.6 g/cm³.

Unlike its physical properties, the mechanical properties of AlBeMet 162 are strongly dependent upon the processing route.

To meet many of the economic requirements imposed by modern designs, that shape or near-net shape processes are required. Investment casting has long been recognized as a process capable of producing parts to near net shape. However, only recently has the capability of investment casting been developed for Al–Be alloy parts. AlBeCast 910 is the first of a family of Al–Be investment casting alloys.

The properties of AlBeCast 910 include 0.2% yield strength of 124 MPa, ultimate tensile strength of 180 MPa, and elongation of 3%.

In addition to conventional processes such as casting and mechanical working, significant progress has been made in adapting new technologies to AlBeMet. The semisolid processing of Al–Be alloys enables the net shape and high production capability of permanent mold die casting for a material whose high melting point and reactivity preclude conventional die casting. As a prototype, a sabot from a 30 mm projectile was semisolid formed, and the uniformity

A

and repeatability of the process was proved out in a semiproduction run of approximately 2500 parts.

The high modulus-to-density ratio, 3.8 times that of aluminum or steel, minimizes flexure and reduces the chance of mechanically induced failure. Therefore, AlBeMet plays a dual role in its avionics applications.

The stiffness, low density, and thermal characteristics of Al-Be alloys combine to produce the highest-performance brake components for the demanding Formula 1 race car circuit, specifically the brake caliper from extrusion. It is the stiffness that is particularly important in such parts, because excessive bending of the caliper leads to reduced braking efficiency. In addition, the thermal management characteristics allow higher and more consistent braking performance than possible with conventional materials.

As a structural material, AlBeMet 162 sheet is being qualified as the rudder material for advanced versions of a U.S. Air Force tactical fighter. In addition, as an essentially isotropic material, it allows simplified design, reduced weight, and increased performance.

Space structures also benefit from AlBeMet, including the OrbComm vehicle. On this satellite, the face sheets for the honeycomb bus (the circular portion of the structure), the brackets that hold the bus to the payload, and the long boom are all fabricated AlBeMet structures.

Aluminum-Scandium Alloys (AlSc)

An AlSc base alloy, Sc 7000, has been developed for use as bicycle frame tubing, shock absorbers, and handlebars. The alloy is 50% stronger than aluminum bicycle alloys and reduces the weight of the bicycle frame by 10%–12%.

New and Special Alloys

Aluminum alloy 7033-T6 is 50% stronger than AA 6061-T6 and provides higher fatigue performance. Developed to provide improved fracture toughness for forgings, the alloy offers corrosion and stress-corrosion properties nearly equal to those of AA 6061-T6 and superior to those of AA 2014-T6.

There are some new Al-Li ingot-cast products, and other P/M wrought alloys. Alcoa's *aluminum alloy C155* is 7% more lightweight and has greater fracture toughness and resistance to fatigue-crack growth than 7075-T651 and 2024-T351. It is also 11% stronger than the latter alloys. Reynolds Metals' *Weldalite* 2195 is 5% more lightweight and 30% stronger than 2219 alloy and has good fracture toughness at cryogenic temperatures. *VacLite* aluminum-lithium alloys, of Comalco Aluminium Limited of Australia, are vacuum-refined alloys having low amounts of hydrogen and alkali metal impurities. Their high purity is believed to account for improved toughness, greater resistance to stress corrosion, and superior weldability, or less tendency for weld cracking than other aluminum-lithium alloys. One of the alloys, with 3.3% lithium, has a tensile yield strength of 504 MPa and a tensile modulus of 83,400 MPa. Aluminum-lithium alloys were developed primarily for aircraft applications. They are used in the horizontal stabilizer of two airbus models and in the cargo floor of the C-17 military transport.

Aluminum Powder

Aluminum powder is produced by drawing a stream of the molten metal through an atomizing nozzle and impinging that stream with compressed air or inert gas, solidifying and disintegrating the metal into small particles, which are then drawn into a collection system

and screened, graded, and packaged. Particle sizes range from –325 mesh (fine) to +200 mesh (granules). In the process, the metal reacts with oxygen in the air and moisture, causing a thin film of Al_2O_3 to form on the surface of the particles. Oxide content, which increases with decreasing particle size, ranges from 0.1% to 1.0% by weight.

First used to produce aluminum flake by ball milling for paint pigments, aluminum powder now finds many other uses: ferrous and nonferrous metals production, P/M parts, P/M-wrought aluminum alloy mill products, coatings for steel, asphalt-roof products, spray coatings, and vacuum metalizing. Other applications include rocket fuels and explosives, incendiary bombs, pyrotechnics, signal flares, and heat and magnetic shields. It is also used in permanent magnets, high-temperature lubricants, industrial cements, chalking compounds, printing inks, and cosmetic and medical products.

Aluminum-Silicon Alloys

Osprey aluminum alloys include a family of machine-readable, lightweight, aluminum-silicon alloys, featuring controlled thermal expansion, high thermal conductivity, electromagnetic or radio-frequency shielding capability, and thermal mechanical stability up to 932°F (500°C). Applications include radio frequency (RF) or microwave housings, electrooptical housings, integrated-circuit power devices, and waveguide- and microwave-filter components. Alloys include *aluminum alloy CE7*, *CE9*, *CE11*, and *CE13*. The numbers in these designations indicate the approximate coefficient of thermal expansion in ppm/°C. Compositions can be customized to thermal expansion requirements. For the common alloys, CE7 contains 7% by weight silicon, CE9 60%, CE11 50%, and CE13 58%.

Supral and DS Alloys

Wrought superplastic alloys, such as Superform Metals' *Supral* alloys and fine-grain *aluminum alloy 7475* or modifications thereof, permit far greater tensile elongation than conventional alloys at low strain rates and temperatures in the 700°F–980°F (371°C–537°C) range, permitting extremely complex shapes to be formed at low gas pressure (0.69–2.1 MPa).

For structural aircraft applications, high-strength alloys such as 2024 and 7075 are generally limited to temperatures below 400°F (204°C). Developmental *dispersion-strengthened aluminum alloys* may extend the range to 600°F (315°C). Key elements of these PM wrought systems include iron and cerium; iron and molybdenum; iron, vanadium, and silicon; or chromium, zirconium, and manganese. All provide tensile yield strengths greater than 270 MPa at 600°F (315°C), the strongest being an aluminum-iron-vanadium-silicon alloy. At room temperature, this alloy has an ultimate tensile strength of 625 MPa, a yield of 568 MPa, and 6% elongation. At 600°F, these values are 310, 300 MPa, and 7%, respectively.

Thixalloy 540, from Salzburger Aluminum AG of Austria, is intended for casting with partially molten alloy. This reduces thermal stress on tooling and solidification shrinkage. The aluminum-magnesium alloy contains 5% silicon, 2% manganese, and some chromium and provides a yield strength of 186 MPa and 18% elongation.

Aluminum Metal Matrix Composites

Aluminum alloys also constitute a major class of *metal-matrix composites*. *Duralcan composites*, from Duralcan USA of Alcan Aluminum Limited, comprise *alumina particulates* in a wrought

matrix alloy and *silicon carbide particulates* in a cast matrix alloy. The amount of particulate pertains to the volume percent. The composites are made by mixing the particulate in a molten alloy, which is then poured into foundry ingot, extrusion billet, rolling bloom, or rolling ingot. These forms are then processed conventionally by casting, extruding, rolling, or forging. Matrix alloys are similar in composition to standard wrought and cast alloys, and all the composites are heat treatable. The composites, however, are stronger, more rigid, harder, and far more wear and abrasion resistant. On the other hand, their ductility and fracture toughness are less, and machining typically requires the use of polycrystalline diamond cutting tools for efficient production. In general, alumina decreases electrical and thermal conductivity and the coefficient of thermal expansion, whereas silicon carbide increases thermal conductivity while decreasing electrical conductivity and thermal expansivity.

Here are some typical properties of extruded bar and rod in the T6 temper; with 15% Al_2O_3 , *aluminum alloy composite 2014 (Duralcan W2A)* has a tensile yield strength of 500 MPa, 2% elongation, and a tensile modulus of 93,800 MPa. Although yield strength is only 6% greater than that of 2014-T6 at room temperature, it is 16%–67% greater in the 200°F–700°F (93°C–371°C) range. *Aluminum alloy composite 2618 (Duralcan W2F)*, with 20% Al_2O_3 , has a yield strength of 420 MPa, 2% elongation, and a modulus of 104,000 MPa. At 400°F (204°C), the yield strength is 320 MPa. With this alumina content, Duralcan W2F has a density of 0.109 lb/in.³ (3017 kg/m³).

In the T4 temper, 15% SiC *aluminum alloy composite X 2080* extrusions have a density of 0.102 lb/in.³ (2823 kg/m³), and ultimate tensile strength of 483 MPa, a yield strength of 365 MPa, 7.5% elongation, and a tensile modulus of 99,978 MPa. With 20% SiC, the density is 1.03 lb/in.³ (2851 kg/m³) and the other properties 517 MPa, 393 MPa, and 6% and 110,320 MPa. With 25% SiC, *aluminum alloy composite 6113* extrusions in the T6 temper have similar density, tensile ultimate and yield strengths of 496 and 438 MPa, respectively, 3% elongation, and a tensile modulus of 120,662 MPa.

Cast Duralcan alloys are based on matrix alloys 339 and 3594 gravity casting and 360 and 380 alloys for die casting. The 359 is for general room-temperature applications, and the 339 is for elevated-temperature applications. Alloy 380 is also for general use, and 360 is for uses requiring additional corrosion resistance. In the T6 temper, *aluminum alloy composite 359 (Duralcan F3S)* with 20% SiC has a tensile yield strength of 340 MPa, 0.4% elongation, and a modulus of 98,600 MPa. Rockwell B hardness is 77, compressive yield strength is also 340 MPa, and the modulus and compression is 101,000 MPa. *Aluminum alloy composite 339 (Duralcan F3K)* with 10% SiC has a yield strength of 360 MPa and a modulus of 87,500 MPa. In the T5 temper, Rockwell B hardness is 63, and the tensile yield strength is 248 MPa at room temperature, 138 MPa at 400°F (204°C), and 69 MPa at 600°F (316°C). In the T5 temper, *aluminum alloy composite 380 (Duralcan F3D)* with 10% SiC has a Rockwell B hardness of 84, a tensile yield strength of 330 MPa, 0.7% elongation, and a tensile modulus of 93,800 MPa. It has a density of 0.100 lb/in.³ (2768 kg/m³).

Boralyn, from Alyn Corp., is *boron carbide–reinforced aluminum alloy* made into billet by isostatic pressing and vacuum sintering powder of conventional wrought alloys and boron carbide (B_4C) particulate followed by extrusion, rolling, forging, or casting. Solution-treated and aged extrusion of *aluminum alloy composite Boralyn H-10*, 10% (B_4C) 6092 alloy, has a density of 0.097 lb/in.³ (2685 kg/m³), a tensile modulus of 84,119 MPa, and ultimate tensile strength of 414 MPa, a tensile yield strength of 345 MPa, and a thermal expansion of 11.7 ppm/°F (21.1 ppm/°C). *Aluminum alloy composite Boralyn H-30*, 30% B_4C 6092, has a density of 0.096 lb/in.³

(2657 kg/m³), a tensile modulus of 120,660 MPa, tensile strengths again of 60,000 lb/in.² ultimate and 50,000 lb/in.² yield, and a thermal expansion of 8.3 ppm/°F (14.9 ppm/°C). *Aluminum alloy composite Boralyn E-10*, 10% B_4C 7083 alloy, has a density of 0.103 (2851 kg/m³), a tensile modulus of 86188 MPa, tensile strengths of 621 MPa ultimate and 586 MPa yield, and a thermal expansion of 11.7 ppm/°F (21.1 ppm/°C).

Composite castings also are made by casting alloys about selectively placed *fiber preforms*. Honda has cast auto engine blocks with alumina and graphite preforms along the cylinder-bore surfaces, eliminating the need for cast iron cylinder liners. *Silicon carbide whiskers* and preforms and have potential for squeeze-cast aluminum composites, especially for military vehicles. *ARALL*, of Alcoa, is a laminate composite comprising thin layers of aramid-reinforced epoxy and wrought high-strength aluminum alloy. Besides being more lightweight than aluminum alloys, the laminate has high fatigue resistance. Variants include *GLARE*, comprising layers of glass-reinforced epoxy and high-strength aluminum alloy, and *CARE*, layers of carbon-reinforced epoxy and high-strength aluminum alloy.

Aluminum Bomb

A bomb-shaped container used in determining the oxygen content in liquid steel.

Aluminum Brass

A wrought copper (76%–79%) and zinc alloy containing 1.8%–2.5% aluminum and 0.022%–0.06% arsenic. The aluminum addition markedly improves the alloy's resistance to impingement attack in high-velocity seawater, and the arsenic inhibits the dezincification. *Aluminum brass C 68700* is commonly used for condensers and heat exchangers and marine applications.

Aluminum Bronze

A series of wrought and *cast copper–aluminum alloys*, most of which also contain several other elements, principally iron. Aluminum content ranges from 4% to 15%, depending on the alloy, and iron, if present, from less than 1%–6%. Alloy designations for *wrought aluminum bronzes* are C60XXX, C61XXX, C62XXX, C63XXX, and C64XXX; cast alloys are C95XXX. The alloys are also referred to by their nominal aluminum content, such as 5% aluminum bronze, or by other distinguishing alloying ingredients, such as *nickel aluminum bronze*. Aluminum bronzes are noted for their moderate to high strength, and corrosion resistance and potable, brackish, and sea waters, industrial and marine atmospheres, and various chemicals. They are attacked, however, by oxidizing acids. Because of their pale gold look and amenability to lustrous finishing, some of the alloys are also used for their decorative appeal. Aluminum bronzes are available in a full range of wrought products, and the cast alloys are amenable to various casting methods. Typical applications include condenser and heat-exchanger tubing and tube sheets, fasteners, shafts, cams, gears, bearings, bushings, valves and valve seats, deep-drawn parts, wear plates, pickling equipment, impellers and agitators, nonsparking hardware, and decorative ware.

Single-phase (alpha) alloys containing only copper and aluminum can only be strengthened by strain hardening during cold working. The 4%–7% *aluminum bronze C60600* alloy in the form of 0.5 in. (13 mm) plate has a tensile yield strength of 115 MPa annealed and 165 MPa in the H04, or “hard,” cold-work temper.

A

In these same conditions, 1 in. (25 mm) diameter rod of *aluminum* (6%–8.5%) *bronze C61000* has a tensile yield strength of 205 and 380 MPa. Two-phase aluminum bronzes, such as those alloying with iron or iron and nickel, are typically strengthened by quenching and then are tempered. One such casting alloy, *aluminum bronze C95500* (nominally 81% copper, 11 aluminum, 4 iron, 4 nickel), as a tensile yield strength of 415 MPa in the quenched and tempered (TQ50) condition, 50% greater than as cast.

Aluminum Nitride (AlN)

A high-thermal conductivity ceramic used as an electronic substrate. Also a key component in the production of *sialons*.

Aluminum Oxide (Al₂O₃)

See *alumina*.

Amalgam

A combination of a metal with mercury. The amalgams have the characteristics that when slightly heated, they are soft and easily workable, and they become very hard when set. They are used for filling where it is not possible to employ high temperatures. Although native amalgams are chemical combinations of the metals, some of the artificial amalgams are alloys and others are compounds. *Dental amalgams* are prepared by mixing mercury with finely divided alloys composed of varying proportions of silver, tin, and copper. A *silver–tin alloy*, developed at the National Institute of Standards and Technology (NIST), is mercury-free and less brittle than standard amalgams. Also promising is NIST's development of fine silver powder that can be compacted and consolidated with conventional dental tools.

Amalgamation Process

A process for the initial extraction of gold and silver. The crushed core is mixed with liquid mercury, which amalgamates with the metals leaving behind the impurities. The amalgam is then heated to drive off the mercury leaving impure gold and silver.

Ambient

The environment that surrounds and contacts a system or component.

American Wire Gauge

A standard used in the determination of the physical size of a conductor determined by its circular-mil area.

Amine

An amine as a member of a group of organic compounds that can be considered as derived from ammonia by replacement of one or more hydrogens by organic radicals. Generally, amines are bases of widely varying strengths, but a few that are acidic are known.

Amines constitute one of the most important classes of organic compounds. The lone pair of electrons on the amine nitrogen enables amines to participate in a large variety of reactions as a base or a nucleophile. Amines play prominent roles in vitamins, for example, epinephrine (adrenaline), thiamine, or vitamin B₁₂ and Novocaine.

Amines are used to manufacture many medicinal chemicals, such as sulfa drugs and anesthetics. The important fiber nylon is an amine derivative.

Aramids are synthetic fibers produced from long-chain polyamides (nylons) in which 85% of the amine linkages are attached directly to two aromatic rings. The fibers are exceptionally stable and have good strength, toughness, and stiffness, which are retained well above 150°C. Two aramids are *Nomex* and *Kevlar* from DuPont Co., and *Twaron* from AkzoNobel NV. They have high strength, intermediate stiffness, and are suitable for cables, ropes, webbings, and tapes. *Kevlar 49*, with high strength and stiffness, is used for reinforcing plastics. *Nomex*, best known for its excellent flame and abrasion resistance, is used for protective clothing, air filtration bags, and electrical insulation.

Amino

Melamine and urea are the principal commercial thermosetting polymers called aminos. The amino resins are formed by an addition reaction of formaldehyde and compounds containing NH₂ amino groups. They are supplied as liquid or dry resins and filled molding compounds. Applying heat in the presence of a catalyst converts the materials into strong, hard products. Aminos are used as molding compounds, laminating resins, wood adhesives, coatings, wet-strength paper resins, and textile-treating resins.

Moldings made from amino compounds are hard, rigid, abrasion resistant, and have high resistance to deformation under load. They have excellent electrical insulation characteristics. Melamines are superior to ureas in resistance to acids, alkalies, heat, boiling water, and for applications involving wet/dry cycling.

Melamines and ureas are not resistant to strong oxidizing acids or strong alkalies, but they can be used safely with conventional household chemicals such as naphtha and detergents. They are unaffected by organic solvents such as acetone, carbon tetrachloride, ethyl alcohol, heptane, and isopropyl alcohol. Petroleum, paraffin hydrocarbons, gasoline, kerosene, motor oil, aromatic hydrocarbons, and fluorinated hydrocarbons (Freon) have no apparent effect on urea and melamine moldings. Dimensional stability is good, but moldings do swell and shrink slightly in varying moisture conditions.

Amino Resins

Resins made by the polycondensation of a compound containing amino groups, such as urea or melamine, within aldehyde, such as formaldehyde, or an aldehyde-yielding material. Melamine formaldehyde and urea formaldehyde resins are the most important family members. The resins can be dispersed in water to form colorless syrups. With appropriate catalysts, they can be cured at elevated temperatures.

Ammeter

An instrument for measuring the magnitude of electric current flow.

Ammonia

A gas of the formula NH₃, originally called *alkaline air* and *volatile alkali*. Ammonia is predominantly made by direct synthesis at high temperatures and pressures of hydrogen and nitrogen, derived by steam reforming hydrocarbons. It is a major building block for making fertilizers, nitric acid, plastics, and explosives. Ammonia is readily absorbed by water, which at 60°F (16°C) takes up 683 times

its own volume of the gas, forming the liquid commonly called ammonia, but which is *ammonium hydroxide*, a colorless, strongly alkaline, and pungent liquid of composition NH_4OH with a boiling point of 100°F (38°C). At 80°F (27°C), it contains 29.4% ammonia in stable solution. It is also known as *ammonium hydrate* and *aqua ammonia*, and it is used for the saponification of fats and oils, as a deodorant, for cleaning and bleaching, for etching aluminum, and in chemical processing.

Ammonia gas is used in refrigeration, in nitriding steels, and in the manufacture of chemicals. Chlorine unites with it to form *chloramines*, which are used as solvents, chlorinating agents, and disinfectants. The gas does not burn in air, but a mixture of ammonia and oxygen explodes when ignited. *Anhydrous ammonia* is the purified gas liquefied under pressure and marketed in cylinders. The anhydrous ammonia used for controlled atmospheres for nitriding steel, bright annealing, and sintering metals contains 90% NH_3 and is oxygen-free.

Smelling salts, sometimes referred to as *ammonia*, and in solution as *aromatic spirits of ammonia*, are *ammonium carbonate*, forming in colorless or white crystals. *Ammonium bicarbonate*, or acid ammonium carbonate, is a water-soluble, white, crystalline powder used as a source of pure ammonia and carbon dioxide and to decrease density inorganic materials by creating voids, such as for making foamed rubber and in the food-baking industry. *Ammonium gluconate* is a water-soluble, white, crystalline powder used as an emulsifier for cheese and mayonnaise and as a catalyst and textile printing.

The ammonium radical, $-\text{NH}_4$, has the chemical reaction of an alkali metal and forms many important chemicals. *Ammonium nitrate* is made by the action of nitric acid on ammonium hydroxide. It is a colorless to white, crystalline, hygroscopic powder of composition NH_4NO_3 , soluble in water, alcohol, and alkalies. It is also used in fertilizers, pyrotechnics, dental gas, insecticides, freezing mixtures, and explosives. For use as a slow-burning propellant for missiles, it is mixed with a burning-rate catalyst and a synthetic-rubber binder and pressed into blocks. *Riv*, a vapor-phase rust inhibitor, is ammonium nitrate. The explosive *amatol* is a mixture of ammonium nitrate and TNT, which explodes violently on detonation. The 50–50 mixture can be melted and poured, while the 80–20 mixture is like sugar and was used for filling large shells. *ANFO*, a mixture of ammonium nitrate and fuel oil formed into porous prills, is one of the largest-selling explosives. *Macite*, for tree trunk blasting, is ammonium nitrate coated with TNT, with a catalyst to make it more sensitive. Akremite is ammonium nitrate and carbon black, used as an explosive in strip mining.

Ammonium perchlorate is another explosive made by the action of perchloric acid on ammonium hydroxide. It is a white crystalline substance of composition NH_4ClO_4 , is soluble in water, and decomposes on heating. *Nitrogen trichloride*, NCl_3 , which forms in reactions of chlorine and ammonia when there is an excess of chlorine, is a highly explosive yellow oil. *Ammonium sulfate*, $(\text{NH}_4)_2\text{SO}_4$, is a gray crystalline, water-soluble material used as a fertilizer and for fireproofing. It is made by reacting sulfuric acid with ammonia by-product from coal distillation, and, increasingly, from sulfuric acid and synthetic ammonia, from caprolactam production, or from gypsum.

Ammonium chloride, or *sal ammoniac*, NH_4Cl , is a white crystalline powder used in electric batteries, in textile printing, as a soldering flux, and in making other compounds. Many salts and metallic soaps are also formed in the same manner as with the alkali metals.

Amorphous

Not having a crystal structure; noncrystalline, that is, the atoms are not arranged in any regular pattern.

Amorphous Metals

Also known as metallic glasses, amorphous metals are produced by rapid quenching of molten metal-metalloid alloys, resulting in a noncrystalline grain-free structure in the form of ribbon or narrow strips. They are extremely strong and hard yet reasonably ductile and quite corrosion resistant. Perhaps of greatest interest is the magnetic performance of several complex iron-based compositions, called *Metglas*. Because of their very low hysteresis and power losses, they can markedly reduce the size of transformer cores traditionally made of silicon steels. Several nickel-alloy compositions also are available for use as brazing foils. One such foil, *Metglas MBF60A*, contains 11% phosphorus and 0.1% maximum carbon and meets *BNi-6 brazing filler* specification of the American Welding Society. For aircraft turbines, it is used as a preform to braze *fiber metal* to 430 stainless steel for abradable seals.

A family of amorphous *zirconium-beryllium alloys* with substantial amounts of titanium, copper, and nickel can be cast into bulk shapes. The alloy family was developed by researchers at the California Institute of Technology and Amorphous Technologies International. The alloy 41Zr–14Ti–12Cu–10Ni has a hardness of 585 H_v . One alloy has exhibited the unusual behavior of giving off intense sparks when struck and broken by impact in air and giving off infrared emissions when struck and broken in a nitrogen atmosphere. This behavior is attributed to the intense heat generated by the highly localized deformation when metallic glasses break. Also, the alloy is not corrosion proof.

Amorcor hardfacing alloys, of Amorphous Metals Technologies, are iron-chromium alloys. There are three basic alloys: alloy M for general corrosion resistance plus resistance to carburization, oxidation, and sulfonation at temperatures up to 1700°F (927°C); alloy C, for resistance to bleach, chlorides, and medium-strength sulfuric acid and to wear, with a maximum use temperature of 1600°F (871°C); and alloy T for especially severe wear applications. The alloys have been used on down-hole drilling pipe and drill bits, engine valve guides, and steelmaking, coal mining, agricultural, and earth-moving equipment.

Amorphous Plastic

A plastic that has no crystalline component, no known order or pattern of molecule distribution, and no sharp melting point.

Amorphous Powder

A powder that consists of particles that are substantially noncrystalline in character.

Amorphous Silicon

A noncrystalline form of silicon or silicon hydride. It is formed as a thin film by chemical vapor deposition and is used as a semiconductor.

Amorphous Solid

A rigid material whose structure lacks crystalline periodicity, that is, the pattern of its constituent atoms or molecules does not repeat periodically in three dimensions. See also *metallic glass*.

Ampere

The unit used for measuring the quantity of an electric current flow. One ampere represents a flow of one coulomb per second.

A

Ampere Turns

The product of the number of turns in an electromagnetic coil and the current and amperes passing through the coil.

Amperometry

Chemical analysis by methods that involve measurements of electric currents.

Amphoterlic

A term applied to oxides and hydroxides, which can act basic toward strong acids and acidic toward strong alkalis. Substances that can dissociate electrolytically to produce hydrogen or hydroxyl ions according to conditions.

Amplifier

A negative lens used instead of an eyepiece to project under magnification the image formed by an objective. The amplifier is designed for flatness of field and should be used with an apochromatic objective.

Amsler Wear Machine

A wear and traction-testing machine consisting of two disk-shaped specimens oriented such that their axes are parallel and whose circumferential, cylindrical surfaces are caused to roll or roll and slide against one another. The rotation rates of each disk may be varied so as to produce varying degrees of sliding and rolling motion.

Amylaceous

Pertaining to, or of the nature of, starch; starchy.

Anaerobic Adhesive

An adhesive that cures only in the absence of air after being confined between assembled parts.

Anaerobic Environments

Containing little or no oxygen.

Analog Circuits

Circuits that provide a continuous (versus discontinuous) relationship between the input and output.

Analog Computer

A computer that processes data that are continuously variable in nature.

Analog-to-Digital Converter

A device that converts a continuously variable electrical signal into discrete signals suitable for analysis by a digital computer.

Analysis

The ascertainment of the identity or concentration, or both, of the constituents or components of a sample. See also *determination*.

Analyte

In any analysis, the substance (element, ion, compound, and so on) being identified or determined.

Analytical Chemistry

The science of chemical characterization and measurement. Qualitative analysis is concerned with the description of chemical composition in terms of elements, compounds, or structural units; quantitative analysis is concerned with the precise measurement of amount. A variety of physical measurements are used, including methods based on spectroscopic, electrochemical, radiochemical, chromatographic, and nuclear principles.

Analytical Curve

The graphical representation of very relationship between (1) the intensity of the response to measurement (e.g., a mission, absorbance, and conductivity) and (2) the concentration or mass of the substance being measured. The curve is generated by measuring the responses for standards of known concentration. Also termed standard curve or working curve.

Analytical Electron Microscopy

The technique of materials analysis in the transmission electron microscope equipped to detect and quantify many different signals from the specimen. The technique usually involves a combination of imaging, chemical analysis, and crystallographic analysis by diffraction at high spatial resolution.

Analytical Gap

The region between two electrodes in which the sample is excited in the sources used for emission spectroscopy and spark source mass spectrometry.

Analytical Line

In spectroscopy, the particular spectral line of an element used in the identification or determination of the concentration of that element.

Analytical Wavelength

In spectroscopy, the particular wavelength used for the identification or determination of the concentration of an element or compound.

Analyzer

An optical device, capable of producing plane polarized light, used for detecting the state of polarization.

Anatomical Materials

Metals and other materials used for long-term insertion into the human body as prostheses, bone reinforcement, etc.

Anchor Pattern

A pattern made by blast cleaning abrasives on an adherend surface in preparation for adhesive application prior to bonding. Pattern is examined in profile.

Anchorage

Part of an insert that is molded inside the plastic and held fast by the shrinkage of the plastic.

Anchorite

A zinc-iron phosphate coating for iron and steel.

Andalusite

A mineral of composition $\text{Al}_2\text{O}_3\text{-SiO}_2$ used in the production of aluminosilicate bricks for use in blast furnaces, steel ladles, and torpedo ladles.

Anelastic Deformation

Any portion of the total deformation of a body that occurs as a function of time when the load is applied and which disappears completely after a period of time when the load is removed.

Anelasticity

The property of solids by virtue of which strain is not a single-value function of stress in the low-stress range where no permanent set occurs.

Angle of Attack

In tribology, the angle between the direction of motion of an impinging liquid or solid particle and the tangent to the surface at the point of impact.

Angle of Bend

The angle between the two legs of the specimen after bending is completed. It is measured before release of the bending force, unless otherwise specified.

Angle of Bevel

See preferred term *bevel angle*.

Angle of Bite

In the rolling of metals, the location where all of the force is transmitted through the rolls; the maximum attainable angle between the roll radius at the first contact and the line of roll centers. Operating angles less than the angle of bite are termed contact angles or rolling angles.

Angle of Contact

In a ball race, the angle between a diametral plane perpendicular to a ball-bearing axis and a line drawn between points of tangency of the balls to the inner and outer rings.

Angle of Incidence

(1) In tribology, the angle between the direction of motion of an impinging liquid or solid particle and the normal to the surface at the point of impact. (2) In materials characterization, the angle between an incident radiant beam and a perpendicular to the interface between two media.

Angle of Nip

In rolling, the *angle of bite*. In roll, jaw, or gyratory crushing, the entrance angle formed by the tangents at the two points of contact between the working surfaces and the (assumed) spherical particles to be crushed.

Angle of Reflection

(1) Reflection: The angle between the reflected beam and the normal to the reflecting surface. See also *normal*. (2) Diffraction: The angle between the diffracted beam and the diffracted planes.

Angle of Repose

The angular contour that a powder pile assumes.

Angle Press

A hydraulic molding press equipped with horizontal and vertical rams, specially designed for the production of complex plastic moldings having deep undercuts.

Angle Wrap

Tape fabric that is wrapped on a starter dam mandrel at an angle to the centerline.

Angle-Ply Laminate

A laminate having fibers of adjacent plies, oriented at alternating angles.

Angstrom Unit (Å)

A unit of linear measure equal to 10^{-10} m, or 0.1 nm. Although not an accepted SI unit, it is occasionally used for small distances, such as interatomic distances, and some wavelengths.

Angular Aperture

In optical microscopy, the angle between the most divergent rays that can pass through a lens to form the image of an object. See also *aperture (optical)*.

Angular-Contact Bearing

A ball bearing of the grooved type, designed in such a way that when under no load, a line through the outer and inner raceway contacts with the balls to form an angle with the plane perpendicular to the bearing axis.

A

Angularity

The conformity to, or deviation from, specified angular dimensions in the cross section of a shape or bar.

Anhydride

A compound from which water has been extracted. An oxide of a metal (basic anhydride) or of a nonmetal (acid anhydride) that forms a base or an acid, respectively, when united with water.

Aniline

An important organic base ($C_6H_5NH_2$) made by reacting chlorobenzene with aqueous ammonia in the presence of a catalyst. It is used in the production of aniline formaldehyde resins and in the manufacture of certain rubber accelerators and antioxidants.

Aniline Formaldehyde Resins

Members of the aminoplastics family made by the condensation of formaldehyde and aniline in an acid solution. The resins are thermoplastic and are used to a limited extent in the production of molded and laminated insulating materials. Products made from these resins have high dielectric strength and good chemical resistance.

Aniline Point

As applied to a petroleum product, the lowest temperature at which the product is completely miscible with an equal volume of freshly distilled aniline. The aniline point is a guide to the oil composition.

Anion

A negatively charged ion that migrates through the electrolyte toward the *anode* under the influence of a potential gradient. See also *cation* and *ion*.

Anisotropic

Exhibiting different properties when tested along axes in different directions. In magnetics, capable of being magnetized more readily in one direction than in a transverse direction.

Anisotropic Conductive Adhesive

Adhesive that can be made conductive in the vertical, or *z*, axis while remaining an insulator in the horizontal, or *x* and *y*, axes.

Anisotropic Laminate

One in which the properties are different in different directions along the laminate plane.

Anisotropy

The characteristic of exhibiting different values of a property in different directions with respect to a fixed reference system in the material.

Anisotropy of Laminates

The difference of the properties along the directions parallel to the length or width of the lamination planes and perpendicular to the lamination.

Anneal (Glass)

To prevent or remove objectionable stresses in glassware by controlled cooling from a suitable temperature.

Anneal to Temper (Metals)

A final partial anneal that softens a cold-worked nonferrous alloy to a specified level of hardness or tensile strength.

Annealed Powder

A metallic powder that is heat treated to render it soft and compactible.

Annealing (Abrasives)

A heating and cooling operation, implying usually a slow cooling to remove stress, to induce softness, to refine structure, or to alter used to secure one or more of the following effects physical properties.

Annealing (Glass)

A controlled cooling process for glass designed to reduce thermal residual stress to a commercially acceptable level and, in some cases, modify structure.

Annealing (Metals)

A generic term denoting a treatment consisting of heating to and holding at a suitable temperature followed by cooling at a suitable rate, used primarily to soften metallic materials, but also to simultaneously produce desired changes in other properties or in the microstructure. The purpose of such changes may be, but is not confined to improvement of machinability, facilitation of cold work, improvement of mechanical or electrical properties, and/or increase in stability of dimensions. When the term is used unqualifiedly, full annealing is implied. When applied only for the relief of stress, the process is properly called *stress relieving* or stress-relief annealing.

In ferrous alloys, annealing usually is done above the upper critical temperature, but the time-temperature cycles vary widely both in maximum temperature attained and in cooling rate employed, depending on composition, material condition, and results desired. When applicable, the following commercial process names should be used: *black annealing*, *blue annealing*, *box annealing*, *bright annealing*, *cycle annealing*, *flame annealing*, *full annealing*, *graphitizing*, *in-process annealing*, *isothermal annealing*, *malleabilizing*, *orientation annealing*, *process annealing*, *quench annealing*, *spheroidizing*, and *some critical annealing*.

And nonferrous alloys, annealing cycles are designed to (1) remove part or all of the effects of cold working (recrystallization may or may not be involved), (2) cause substantially complete coalescence of precipitates from solid solution in relatively coarse form, or (3) both, depending on composition of a material condition.

Specific process name of a commercial use are *final annealing*, *full annealing*, *intermediate annealing*, *partial annealing*, *recrystallization annealing*, *stress-relief annealing*, and *anneal to temper*.

Annealing (Plastics)

Heating to a temperature at which the molecules have significant mobility, permitting them to reorient to a configuration having less residual stress. In semicrystalline polymers, heating to a temperature at which retarded crystallization or recrystallization can occur.

Annealing Carbon

See *temper carbon*.

Annealing Point (Glass)

The temperature at which internal stresses in a glass are substantially relieved in a matter of minutes.

Annealing Range (Glass)

The range of glass temperature in which stress in glass can be relieved at a commercially practical rate. For purposes of comparing glasses, the annealing range is assumed to correspond with the temperature between the annealing point and the strain point.

Annealing Twin

A *twin* formed in a crystal during recrystallization.

Annealing Twin Bands

See *twin bands*.

Annular Bearing

(1) Usually a rolling bearing of short cylindrical form supporting a shaft carrying a radial load. (2) A flat disk-shaped bearing.

Anode

(1) The electrode of an electrolyte cell at which oxidation occurs. Electrons flow away from the anode in the external circuit. It is usually at the electrode that corrosion occurs and metal ions enter solution. (2) The positive (electron-deficient) electrode in an electrochemical circuit. In contrast with *cathode*.

Anode Aperture

In electron microscopy, the opening in the accelerating voltage anode shield of an electron gun through which the electrons must pass to illuminate or irradiate the specimen.

Anode Compartment

In an electrolytic cell, the enclosure formed by a diaphragm around the anodes.

Anode Copper

Special-shaped copper slabs, resulting from the refinement of *blister* copper in a reverberatory furnace, used as anodes in electrolytic refinement.

Anode Corrosion

The dissolution of a metal acting as an *anode*. Corrosion at the anode of an electrolytic cell, the normal site and wet environments.

Anode Corrosion Efficiency

The ratio of the actual corrosion (weight loss) of an *anode* to the theoretical corrosion (weight loss) calculated by *Faraday's law* from the quantity of electricity that is passed.

Anode Effect

The effect produced by polarization of the *anode* and electrolysis. It is characterized by a sudden increase in voltage and a corresponding decrease in amperage due to the anode becoming virtually separated from the electrolyte by a gas film.

Anode Efficiency

Current efficiency at the *anode*. The observed rate of anode dissolution as a percentage of the theoretical rate predicted by *Faraday's laws of electrolysis*.

Anode Film

(1) The portion of solution in immediate contact with the *anode*, especially if the concentration gradient is steep. (2) The outer layer of the anode itself.

Anode Metals

Metals used for the positive terminals in electroplating. They provide in whole or in part the source of the metal to be plated, and they are as pure as commercially possible, uniform in texture and composition, and have the skin removed by machining. They may be either cast or rolled, with their manufacture controlled to obtain a uniform grade and to exclude impurities, so that the anode will corrode uniformly in the plating bath and not polarize to form slimes or crusts. In some plating, such as for white bronze, the anode efficiency is much higher than the cathode efficiency, and a percentage of steel anodes is inserted to obtain a solution balance. In other cases, as in chromium plating, the metal is taken entirely from the solution, and insoluble anodes are employed. Chromium-plating anodes may be lead-antimony, with 6% antimony, or tin-lead, with 7% tin. In addition to pure single metals, various alloys are marketed in anode form. The usual brass is 80% copper and 20% zinc, but other compositions are used, some containing 1–2 tin. *Brass anodes* are called *platers' brass*. *Copper anodes* for metal plating are usually hot-rolled oval bars, 99.9% pure, while those for electro-type deposits may be hot-rolled plates, electrodeposited plates, or cast plates. *Copper ball anodes* are forged instead of cast to give a finer and more even grain. *Zinc anodes* are 99.99% pure. *Nickel anodes* are more than 99% pure, rolled or cast in iron molds, or 97% sand cast. *Bright nickel* anodes have 1% or more of cobalt. *Lead anodes* have low current-carrying capacity and may be made with a saw-tooth or multiple-angled surface and ribs, to provide more area and give greater throwing power. Anodes of other metals are also made with sections gear-shaped, fluted, or barrel-shaped to give greater surface area and higher efficiency. *Rhodium anodes* are made in expanded-mesh form. *Platinum anodes*, also made in mesh form, have the platinum clad on tantalum wire. Special anode metals are marketed under trade names, usually accenting the color, hardness, and corrosion resistance of the deposit plate.

A

Anode Mud

Deposit of insoluble residue formed from the dissolution of the anode and commercial electrolysis. Sometimes called anode slime.

Anode Polarization

See *polarization*.

Anodic Cleaning

Pickling cleaning of a metal in an electrolytic cell in which the component forms the anode receiving an electrical current from an external source. Electrolytic cleaning in which the work is the anode. Also called reverse-current cleaning.

Anodic Coatings

Anodic oxidation or anodizing is the common commercial term used to designate the electrolytic treatment of metals in which stable oxide films or coatings are formed on surfaces. Aluminum and magnesium are anodized to the greatest extent on a commercial basis. Some other metals such as zinc, beryllium, titanium, zirconium, and thorium can also be anodized to form films of varying thicknesses, but they are not used to any large extent commercially.

Aluminum

It is a well-known fact that a thin oxide film forms on aluminum when it is exposed to the atmosphere. This thin, tenacious film provides excellent resistance to corrosion. The ability of aluminum to form an adherent oxide film led to the development of electrochemical processes to produce thicker and more effective protective and decorative coatings.

Anodic coatings can be formed on aluminum in a wide variety of electrolytes utilizing either AC or DC current or combinations of both. Electrolytes of sulfuric, oxalic, and chromic acid's are considered to be the most important commercially. Other electrolytes such as borates, citrates, chromates, bisulfates, phosphates, and carbonates can also be used for specialized applications.

Anodic coatings produced in a sulfuric acid type of electrolyte are generally translucent, can be produced with a wide range of properties by varying operating techniques, and have a greater number of pores that are smaller in diameter than other anodic coatings.

Coatings obtained by the chromic acid anodic process are much thinner than those produced by the sulfuric acid process based upon the same time of anodic oxidation. Although the coatings are thin, they provide high resistance to corrosion because of the presence of chromium compounds in combination with their relatively thick barrier layer. Because the conventional anodic coatings produced in a chromic acid electrolyte are thin, they have low resistance to abrasion but a high degree of flexibility.

The chromic acid anodic process is critical with respect to alloy composition. In general, the process is not recommended for aluminum alloys containing more than 7% Si or 4.5% Cu. Alloys containing over 7% total alloying elements are also not recommended. It is difficult to form films on these alloys, particularly on casting alloys. Anodic solution (surface attack) will generally occur unless the processing conditions are controlled very carefully.

On most aluminum alloys, anodic coatings of this type do not require sealing. However, sealing in a boiling die chromate or a dilute chromic acid solution produces coatings with the best resistance to salt spray corrosion on AA 2014-T6 and AA 7075-T6 alloys.

Anodic oxidation and dilute oxalic acid solutions produce coatings that are essentially transparent. Their color varies from a light yellow to bronze. Such coatings are dense and have little absorptive capacity but possess high resistance to abrasion.

Hard Coatings

Procedures have been developed that produce finishes of greater thickness and density than the conventional anodic coatings. They have high resistance to abrasion, erosion, and corrosion. The coatings have thicknesses in the range of 0.1–5 mils, depending upon the application.

Hard coatings are popular for applications requiring lightweight in combination with high resistance to wear, erosion, and corrosion. These applications include helicopter rotor blade surfaces, pistons, pinions, gears, cams, cylinders, impellers, turbines, and many others. Also, due to their attractive gray color, hard anodic coatings are now being used for architectural applications.

The processing conditions for obtaining hard coatings are such that thick coatings with maximum density can be obtained on most aluminum alloys. The selection of alloy is of utmost importance.

Variations of the anodic oxidation process that produce conventional hard anodic coatings also form thick, dense, colored anodic coatings for architectural applications. Attractive bronze, gray, or black coatings are obtained by utilizing certain organic acids as electrolytes.

Other Coatings

Utilizing oxalic acid in combination with titanium, zirconium, and thorium salts for the electrolyte produces a dense oxide coating that has an opaque, light-gray appearance.

Anodic oxidation of aluminum in sulfamic acid produces coatings that are denser than those produced by the sulfuric acid process. This anodic process is expensive owing to the high cost of sulfamic acid.

Alternating current may be used to form anodic coatings on aluminum and alloys with all of the electrolytes previously mentioned, but the aluminum surface is anodic only half of the cycle so that an oxide coating is formed only at half the rate of coatings formed with direct current.

Superimposed AC–DC has also been used for anodizing and has produced hard, thick, anodic coatings.

Alloy Selection

The previous discussion on the anodic oxidation characteristics of various electrolytes was based upon the use of relatively pure aluminum. Alloy selection is important. Even aluminum of 99.3% minimum purity, such as the AA1100 alloy, is in a sense an aluminum alloy from the standpoint of anodic oxidation, because the other elements present have an effect on the characteristics of the coating.

The response of the different constituents of aluminum alloys varies considerably and is an important factor. Some constituents will be dissolved by the anodic reaction, whereas others may be unaffected. For alloys where the constituents are dissolved during the anodic treatment, the coatings will have voids that decrease the density of the coating and also lower its resistance to corrosive action and abrasion. Al–Cu alloys are an example of this type.

Silicon in Al–Si alloys is an example of a constituent that is unaffected by conventional anodic oxidation. The silicon particles remain unchanged in the coating in their original position.

Some constituents of aluminum alloys will themselves oxidize under anodic oxidation and the oxidation products will color the coating. For example, constituents such as manganese will produce a

brownish opaque appearance due to the presence MnO_3 . Also, chromium as a constituent will give a yellowish tint to the coating from oxidation products of chromium.

The lower the concentration of constituents present or the purer the aluminum, the more continuous and transparent will be the oxide coating. The so-called superpurity (99.99%) aluminum produces the most transparent oxide coating.

Properties and Applications

The oxide coatings produced by anodizing have many properties that make them commercially important. Anodic coatings are essentially Al_2O_3 , which is a very hard substance. Because the Al_2O_3 is integral with the surface, it will not chip or peel from the surface; this outstanding characteristic is useful for architectural applications. The combination of high wear resistance and attractive satin sheen of the finish makes it a logical choice for aluminum hardware, handrails, moldings, and numerous other architectural components. Because the anodic finish reproduces the texture of the surface from which it is formed, a wide variety of attractive effects are possible by variation in the surface preparatory procedures. Many commercial architectural applications can use a natural aluminum finish, but for applications where it is desirable to preserve initial appearance, the anodic finish will require less maintenance.

Because the oxide coating is brittle compared with the aluminum underneath, it will crack if the coated article is bent. It is possible, however, to produce oxide coatings that are relatively flexible. In general, the thicker coatings formed in sulfuric and oxalic acid electrolytes will crack or craze to a much greater extent than oxide coatings formed in a chromic acid electrolyte. For many applications, this cracking may not be objectionable, because it is usually difficult to detect by visual observation. These fine cracks have an adverse effect on the bending properties of the metal, however, and may sometimes cause fracture if the bends are severe. For this reason, it is generally recommended that the finish be applied after forming.

If fatigue is a critical factor, then proper allowance must be made for the reduction in endurance limits produced by relatively thick oxide coatings. Fatigue tests indicate that a coating 0.1 mils thick on smooth surfaces will have little effect on fatigue strength. Thicker coatings in the range of 0.3–0.5 mils on smooth surfaces have a slight detrimental effect at high stresses.

Anodic coatings also provide substantial protection against corrosion. There are many factors that must be considered in this connection such as the continuity of the coating and the choice of alloy. Since continuity is dependent upon constituents present in the alloy, anodic coatings on high-purity aluminum are the most resistant to corrosion. On the other hand, anodic coatings formed from Al–Cu alloys have much lower resistance to corrosion.

Sealing of anodic coatings in dichromate solutions results in an appreciable improvement in resistance to corrosion, particularly by chlorides. The results of atmospheric exposure tests indicate that anodic coatings with a thickness of 0.4 mils or greater will provide greatly increased resistance to weathering.

The ability of anodic coatings to absorb coloring substances such as dyestuffs and pigments makes it possible to obtain finishes in a complete range of colors including black. The colors are unique because the luster of the underlying metals gives them a metallic sheen that is particularly attractive for applications that simulate metals such as gold, copper, bronze, and brass. Colorants are available that, when used to color anodic coatings on the proper alloys, will reproduce the natural colors of the metals listed earlier. Colored finishes can be used in a wide range of applications for nameplates, panels, and appliance trim, optical goods, cameras, fishing reels, instruments, giftware, and jewelry.

Anodic coatings have good electrical insulating properties. Anodic films produced in boric acid electrolytes are used commercially on aluminum foil for electrical capacitors. The voltage necessary to break down the anodic coatings is generally proportional to the thickness.

Anodic oxidation in oxalic acid and phosphoric acid electrolytes produces coatings that have been successfully used as preparatory treatments for electroplating. Copper, nickel, cadmium, silver, and iron have been successfully deposited over oxide coatings. Plating solutions that are highly alkaline should be avoided as they attack the coating and destroy the porous structure necessary for the best adhesion.

A “Krome-Alume” process utilizes an oxalic acid electrolyte to form the oxide coating, and subsequent modification of the coating with hydrofluoric acid produces a structure satisfactory for electroplating. Furthermore, the anodic oxidation process utilizing a phosphoric acid electrolyte produces a structure that requires no further modification to condition it for electroplating. The alloy has an important effect on coating structure, and in general, the phosphoric anodic process is not recommended for preparing high-purity aluminum, Al–Mg wrought alloys, and most die-casting alloys for electroplating.

Production Methods

Anodic coatings are applied to aluminum and its alloys by a variety of methods, including batch, bulk, continuous conveyor, and continuous strip.

The batch method of applying anodic coatings is similar to that used in electroplating except that the parts are anodic instead of cathodic. The continuous conveyor method is also similar to the conventional plating method.

The bulk method for applying anodic coatings to small parts such as rivets, washers, and screws is radically different from bulk electroplating methods. The barrel-finishing method is not suitable for applying anodic coatings because the initial flow of current forms an anodic coating on the parts and even if they contact each other during the rotation of the barrel, no current will flow because the coating is an insulator. The bulk methods employed for anodic coatings utilize special perforated nonmetallic cylindrical containers. Pressure, applied to the parts in the container through a threaded center contact post, maintains the initial contact between the surface of the parts.

The continuous strip process has been used commercially to apply anodic coatings to aluminum sheet that is subsequently roll formed into weather strip. In Europe, the same process is used to apply anodic coatings to aluminum sheet that is formed into food containers such as sardine cans.

Magnesium

Although all of the magnesium alloys in commercial use today have good resistance to corrosion, many parts are provided with maximum resistance to corrosion and abrasion through electrolytic treatments based on anodic treatments. The anodic treatments produce relatively thick and dense coatings with excellent adhesion and high resistance to corrosion and abrasion. As in the case of aluminum, anodic coatings on magnesium alloys are an excellent base for lacquers and enamels.

It is well known that magnesium alloys are attacked by most inorganic and organic acids. However, because magnesium alloys are resistant to alkalis, fluorides, borates, and chromates, the electrolytes for oxidizing are generally based upon these chemicals.

A

The simplest electrolyte for anodizing magnesium alloys is a 5% caustic soda solution. This electrolyte is used in a temperature range of 60°C–70°C. A voltage of 5–6 is satisfactory; anodic oxidation time is generally 30 min. All magnesium alloys will respond to this treatment. The coatings produced are approximately 0.3 mils thick and are essentially crystalline magnesium hydroxide. They have relatively high resistance to abrasion and are gray or tan in color in the as-formed condition. The coatings may be colored for decorative applications by immersion in water-soluble dyestuffs in much the same way as the coloring procedures used for anodic coatings on aluminum alloys. If maximum resistance to corrosion is required, immersion (sealing) in a 5% sodium chromate solution at 77°C–82°C is recommended.

Another anodizing treatment for magnesium alloys capable of producing a coating with many desirable properties is the “H.A.E.” process. This process is also based upon an alkaline electrolyte. All magnesium alloys, both wrought and cast, respond to this process to give coatings with excellent resistance to corrosion, high dielectric strength, and high hardness.

Other Metals

Thin oxide films may be formed on beryllium by anodic oxidation in an electrolyte composed of 10% nitric acid containing 200 g/L of chromic acid. The anodic oxidation is carried out at approximately 25 A/ft². Such films retard high temperature oxidation and corrosion.

Thin oxide films can also be formed on zirconium, titanium and thorium by anodizing in an electrolyte composed of 70% glacial acetic and 30% nitric acid. The corrosion resistance of titanium is substantially improved by anodizing for 10–15 min in a 15%–22% (by weight) sulfuric acid solution (room temperature) at approximately 18 V DC. Anodic coatings on titanium are also used as a base for lubricants.

Zinc

Much of the work on anodic coatings for zinc has been conducted in alkaline electrolytes consisting of a two-stage process. The electrolyte for the first oxidation treatment is conducted in an alkali-carbonate solution followed by anodizing in a silicate solution.

Anodic Etching

Development of microstructure by selective dissolution of the polished surface under application of a direct current. Variation with layer formation; anodizing.

Anodic Inhibitor

A chemical substance or mixture that prevents or reduces the rate of the anodic or oxidation reaction. See also *inhibitor*.

Anodic Oxidation

See *anodizing*.

Anodic Pickling

Electrolytic pickling in which the work is the anode.

Anodic Polarization

The change of the electrode potential in the noble (positive) direction due to current flow. See also *polarization*.

Anodic Protection

(1) A technique to reduce the corrosion rate of a metal by polarizing it into its passive region, where dissolution rates are low. (2) Imposing an external electrical potential to protect a metal from corrosive attack. Normally, anodic areas would be expected to corrode. (Applicable only to metals that show active-passive behavior.) In contrast with *cathodic protection*.

Anodic Reaction

Electrode reaction equivalent to a transfer of positive charge from the electronic to the ionic conductor. An anodic reaction is an oxidation process. An example common in corrosion is $\text{Me} \sim \text{Me}^{n+} + n\text{e}^-$.

Anodizing

The process of forming a conversion coating on a metal surface by anodic oxidation; this oxide film of greater thickness than normal makes the component, usually aluminum, the anode, and electrolytic cell carrying an electric current from an external source. See *electrochemistry*. A freshly exposed surface of aluminum will normally develop a thin, hard, tenacious oxide film, which resists further corrosion. The thicker film produced by anodizing, typically 0.01 mm, has improved resistance to abrasion and corrosion and can be dyed various colors.

Anolyte

The electrolyte adjacent to the *anode* and *electrolytic cell*.

Antechamber

The entrance vestibule of a continuously operating sintering furnace.

Antielastic Deformation

The deformation experienced in the transverse plane when a beam is bent in the longitudinal plane. Bending induces compressive stresses at the exterior of the bend and compression at the interior. In the case of a simple rectangular beam, the exterior face of the longitudinal curve tends to become concave and the interior face to become convex while the sides taper out toward the inner face.

Anticorrosive Additive

A lubricant additive used to reduce corrosion.

Antiextrusion Ring

A ring that is installed on the low-pressure side of a seal or packing, in order to prevent extrusion of the sealing material.

Antiferromagnetic Material

A material wherein interatomic force holds the elementary atomic magnets (electron spins) of a solid in alignment, a state similar to

that of a *ferromagnetic material* but with the difference that equals numbers of elementary magnets (spins) face in opposite directions and are antiparallel, causing the solid to be weakly magnetic, which is paramagnetic, instead of ferromagnetic.

Antifoam Additive

An additive used to reduce or prevent foaming. Also known as *foam inhibitor*.

Antifouling

Intended to prevent fouling of underwater structures, such as the bottom of ships.

Antifouling Coatings

Applied to the immersed surfaces of vessels and other immersed structures to inhibit adhesion by marine organisms. The term usually implies materials that have a toxic component that is continuously released to poison or at least deter organisms.

Antifreeze Compounds

Materials employed in the cooling systems and radiators of internal combustion engines to ensure a liquid circulating medium at low temperatures to prevent damage from the formation of ice. The requirements are that the compound give a freezing point below that is likely to be encountered without lowering the boiling point much below that of water, that it does not corrode the metals or deteriorate rubber connections, that it be stable up to the boiling point, and that it be readily obtainable commercially. Calcium chloride was earlier used for automobile radiators but corroded the metals. It is still used in fire tanks, sodium chromate being added to retard corrosion. Oils were also used, but the high boiling points permitted overheating of the engine, and the oils softened the rubber. Denatured *ethyl alcohol* may be used, but *methanol* is less corrosive and less expensive. A 30% solution of ethyl alcohol in water has a freezing point of about 5°F (−15°C), and a 50% solution freezes at −24°F (−31°C). Alcohol, however, must be renewed frequently because of loss by evaporation.

Glycerol is also used as an antifreeze, a 40% solution in water lowering the freezing point to about 0°F (−18°C) and a 50% solution to −15°F (−25°C). It has the disadvantage of high viscosity, requiring forced circulation at low temperatures, but it does not evaporate easily. *Ethylene glycol* lowers the freezing point to a greater extent than alcohol but has a high boiling point so that it is not lost by evaporation, but it has a higher first cost and will soften ordinary natural rubber connections. *Acetamide* in water solution may also be used as an antifreeze. Antifreezes are sold under various trade names. *Zerone*, of DuPont, as a methanol base, while *Zerex* has a base of ethylene glycol. *Prestone*, marketed by Union Carbide Corp., is ethylene glycol antifreeze. *Pyro* is an antifreeze of U.S. Industrial Chemicals, Inc., with a low freezing point. *Ramp* is ethylene glycol with anticorrosion and antifungal agents added. *Antifreeze PFA55MB*, of Phillips Petroleum Co., used in jet engine fuels, is ethylene glycol monoethyl ether with 10% glycerin. *Dowtherm 209*, of Dow Chemical Co., is an antifreeze material of inhibited methoxypropanol, which boils off without forming gum. *Sierra*, a propylene glycol-based antifreeze of Safe Brands Corp., performs as well as ethylene glycol compounds but is less toxic. A 50–50 blend with water freezes at −26°F (−32°C).

Antifriction Alloys

Tin-, lead-, aluminum- and zinc-base alloys having a low coefficient of friction in contact with, particularly, steel.

Antifriction Bearing

A bearing containing a solid lubricant. An imprecise term often indicating only that the bearing option under discussion is better than the previous practice. In very general terms, friction reduces in the sequence metal to metal, plain bearing such as white metal, rolling element bearing, air bearing and magnetic levitation, ditto in vacuum, the first three being vastly improved by lubrication. See also *roller bearing*, *rolling-element bearing*, and *self-lubricating bearing*.

Antifriction Material

A material that exhibits low-friction or self-lubricating properties.

Antimonial Alloys

Alloys containing large quantities of antimony. The two classes of alloy best meriting the description are the very hard and relatively brittle antimony-based bearing alloys with about 25% copper or 15% tin and 5% copper and the lead-based alloy with up to about 30% antimony for chemical plant applications. The tin-based *Babbitt metals* also contain antimony but in lesser amounts.

Antimony

Antimony is a bluish-white metal, symbol Sb, with a crystalline scalelike structure that exhibits poor electrical and heat conductivity. It is brittle and easily reduced to powder. It is neither malleable nor ductile and is used only in alloys or in its chemical compounds. Like arsenic and bismuth, it is sometimes referred to as a metalloid, but in mineralogy, it is called a semimetal. The element is available commercially and 99.999+ percent purity and is finding increasing use in semiconductor technology.

Antimony is produced either by roasting the sulfide with iron or by roasting the sulfide and reducing the sublimate of Sb_4O_6 thus produced with carbon: high-purity antimony is produced by electrolytic refining. Antimony is one of the few elements that exhibit the unique property of expanding on solidification. Antimony is ordinarily stable and not readily attacked by air or moisture. Under controlled conditions, it will react with oxygen to form oxides. The chief uses of antimony are in alloys, particularly for hardening lead-base alloys.

Antimony imparts hardness and a smooth surface to soft-metal alloys, and alloys containing antimony expand on cooling, thus reproducing the fine details of the mold. This property makes it valuable for type metals. When alloyed with lead, tin, and copper, it forms the *Babbitt metals* used for machinery bearings. It is also much used in white alloys for pewter utensils. Its compounds are used widely for pigments.

Antioxidant

Any additive for the purpose of reducing the rate of oxidation and subsequent deterioration of a material. Antioxidants embrace a wide variety of materials, but in general, for antioxidant activity, the hydroxy groups must be substituted directly in an aromatic nucleus.

A

In the phenol group of antioxidants, the hydrogen atoms must be free. In the naphthol group, the alpha compound is a powerful antioxidant. Usually, only minute quantities of antioxidants are used to obtain the effect.

Since odor is a major component of flavor, and the development of unpleasant odors in edible fats arises from oxidation, the use of antioxidants is generally necessary, and such for use they are called *food stabilizers*. But degradation of some organic materials may not be a simple oxidation process. In polyvinyl chloride plastics, the initial stage of heat degradation is a dehydrochlorination with hydrogen chloride split out of the molecular chain to give a conjugated system subject to oxidation. Materials called *stabilizers* are thus used to prevent the initial release. Traces of iron and copper in vegetable oils promote rancidity, and citric acid is used as a stabilizer in food oils to suppress this action.

The term *corrosion inhibitors* usually refer to materials used to prevent or retard the oxidation of metals. They may be elements alloyed with the metal, such as columbium or titanium incorporated in stainless steels to stabilize the carbon and retard intergranular corrosion, or they may be material applied to the metal to retard oxygen attack from the air or from moisture. Many paint undercoats, especially the phosphate and chromate coatings applied to steel, are corrosion inhibitors. They may contain a ferrocyanide synergist.

Imidazole and *benzatriazole* systems are *copper antioxidants* used as alternatives to lead-tin solderable surfaces on printed wiring boards.

Antipitting Agents/Compound

An addition agent added to solutions used for pickling, electroplating, etc., to prevent pitting of the component being treated or large pores in the electrodeposit.

Antiscuffing Lubricant

A lubricant that is formulated to avoid scuffing. See also *extreme-pressure lubricant*.

Antiseizure Property

The ability of a bearing material to resist seizure during momentary lubrication failure.

Antislip Metals

Metals with abrasive grains cast or rolled into them, used for floor plates, stair treads, and car steps. They may be of any metal but are usually iron, steel, bronze, or aluminum. The abrasive may be sand, but it is more usually a hard and high-melting-point material such as aluminum oxide. In standard cast forms, antislip metals are marketed under trade names. *Alumalun* is the name of an aluminum alloy cast with abrasive grains. *Brozalum* is a similar product made of bronze. *Algrip steel* is steel plate with abrasive grains rolled into one face. It is used for loading platforms and ramps.

Antistatic Agents

Agents that, when added to a plastic molding material or applied to the surface of a molded object, make it less conductive, thus hindering the fixation of dust or the buildup of electrical charge.

Anti-Stokes Raman Line

A Raman line that has a frequency higher than that of the incident monochromatic radiation.

Antiwear Additive

A lubricant additive used to reduce wear.

Antiweld Characteristic

See *antiseizure property*.

Anvil

A large, heavy metal block that supports the frame structure and holds the stationary die of a forging hammer. Also, the metal block on which blacksmiths forgings are made. Alternatively, a pair of surfaces that both move to retain or manipulate a component.

Anvil Cap

Same as *sow block*.

Aperture (Electron)

See *anode aperture*, *condenser aperture*, and *physical objective aperture*.

Aperture (Optical)

In optical microscopy, the working diameter of a lens or a mirror. See also *angular aperture*.

Aperture Size

The opening of a mesh as in a sieve. See also *sieve analysis*.

Apiezon Oil

An oil of low vapor pressure used in vacuum technology.

API Gravity (API Degree)

A measure of density used in the U.S. petroleum industry where $\text{degrees API} = (141.5/\text{specific gravity at } 60^\circ\text{F}) - 131.5$.

Aplanatic

Corrected for spherical aberration and coma.

Apochromatic Lens

A lens whose secondary chromatic aberrations have been substantially reduced. See also *achromatic*.

Apochromatic Objective

Objectives corrected chromatically for three colors and spherically for two colors are called apochromats. These corrections are superior to those of the achromatic series of lenses. Because apochromats

are not well corrected for lateral color, special eyepieces are used to compensate. See also *achromatic*.

Apparent Area of Contact

In tribology, the area of contact between two solid surfaces defined by the boundaries of their macroscopic interface. In contrast with *real area of contact*. See also *Hertzian contact area* and *nominal contact area*.

Apparent Density

(1) The weight per unit volume of a powder, in contrast to the weight per unit volume of the individual particles. (2) The weight per unit volume of a porous solid, where the unit volume is determined from external dimensions of the mass. Apparent density is always less than the true density of the material itself.

Apparent Hardness

The value obtained by testing a sintered object with standard indentation hardness equipment. Because the reading is a composite of pores and solid material, it is usually lower than that of a wrought or cast material of the same composition and condition. Not to be confused with *particle hardness*.

Apparent Pore Volume

The total pore volume of a loose powder mass or a green compact. It may be calculated by subtracting the apparent density from the theoretical density of the substance.

Apparent Porosity

The relation of the open pore space to the bulk volume, expressed in percent.

Approach Distance

The linear distance, in the direction of feed, between the point of initial cutter contact and the point of full cutter contact.

Aqua Regia

A mixture of 25% nitric acid and 75% HCl by volume.

Aqueous

Relating to water, for example, a water environment or water-based solution.

Aramid (Aromatic Polyamide)

Aramid fibers are characterized by excellent environmental and thermal stability, static and dynamic fatigue resistance, and impact resistance. These fibers have a higher specific tensile strength (strength/density ratio) of any commercially available continuous-filament yarn. Aramid-reinforced thermoplastic composites have excellent wear resistance and near-isotropic properties—characteristics not available with glass or carbon-reinforced composites.

They are synthetic fibers mainly produced from long-chain polyamides (nylons) in which 85% of the amide linkages are attached directly to two aromatic rings. These are the *poly(isophthaloylchloride/m-phenylenediamine)* meta-aramid *Nomex* and the *poly(terephthaloylchloride/m-phenylenediamine)* para-aramid *Kevlar* from DuPont and the para-aramid *Twaron* from AkzoNobel. The fibers are not biodegradable, not toxic to aquatic life, and pose no unusual hazard in a spill or fire. *Nomex*, creamy white naturally but producible to customer color specifications, and gold-colored *Kevlar* are composed mainly of carbon, oxygen, nitrogen, and hydrogen. Both are insoluble in water and neither melts.

Aramid fiber, tradenamed *Kevlar*, is available in several grades and property levels for specific applications. The grade designated simply as *Kevlar* is made specifically to reinforce tires, hoses, and belting, such as V-belts and conveyor belts.

Kevlar 29 is similar to the basic *Kevlar* in properties but is designated specifically for use in ropes and cables, protective apparel, and as the substrate for coated fabrics. In short fiber or pulp form, *Kevlar 29* can substitute for asbestos in friction products or gaskets. Fabrics of *Kevlar 29* can be made into bullet-resistant vests. Clothing made from *Kevlar 29* can be as heat resistant as that made from asbestos and also be extremely cut resistant.

Kevlar 49 has half the elongation (2.5%) and twice the modulus (117, 885 MPa) of *Kevlar 29*. Applications are principally in reinforcing plastic compounds used in lightweight aircraft, boat hulls, and sports equipment. Composites containing *Kevlar* also used as interior panels and secondary structural parts, such as fairings and doors on commercial aircraft.

Kevlar 149 is a highly crystalline aramid that has a modulus of elasticity 40% greater than that of *Kevlar 49* and a specific modulus nearly equal to that of high-tenacity graphite fibers. It is used to reinforce composites for aircraft components. See Table A.14.

Nomex aramid fiber is characterized by excellent high-temperature durability with low shrinkage. It will self-extinguish and

TABLE A.14
Properties of Aramid Fibers

Material	Density (g/cm ³)	Filament Diameter		Tensile Modulus ^a		Tensile Strength ^a		Tensile Elongation (%)	Available Yarn Count, No. Filaments
		μm	μin.	GPa	10 ⁶ psi	GPa	10 ⁶ psi		
Kevlar 29 (high toughness)	1.44	12	470	83	12	3.6 2.8 ^b	0.525–0.400 ^b	4.0	134–10,000
Kevlar 49 (high modulus)	1.44	12	470	131	19	3.6–4.1	0.525–0.600	2.8	134–5,000
Kevlar 149 (ultrahigh modulus)	1.47	12	470	186	27	3.4	0.500	2.0	134–1,000

^a ASTM D 2343, impregnated strand.

^b ASTM D 885, unimpregnated strand.

A

does not melt, retaining a high percentage of its initial strength at elevated temperatures. It is available as continuous-filament yarn, staple, and tow. *Nomex* is used in military and civilian applications such as protective apparel, dry gas filtration, rubber reinforcement, and industrial fabrics. *Nomex* aramid fibers are also available as a paper for use in high-temperature electrical insulation and resilient, corrosion-proof honeycomb core for aerospace, and other transportation applications.

Nomex fiber products include staple and filament forms, the staple being the material totally, the material with as much as 60% *Kevlar*, or blends of those materials with antistatic fibers. *Nomex Omega* refers to firefighters' protective clothing of thermal inner liner, moisture barrier, air, and outer shell. Other forms, or products, are yarn, fabric, tow, and floc.

Arbitration Bar

A test bar, cast with a heat of material, used to determine chemical composition, hardness, tensile strength, and the deflection and strength under transverse loading in order to establish the state of acceptability of the casting. It is intended for destructive examination as a check on the component quality. In the case of castings, the bar will be from the same melt as the component. In other cases, a bar sourced from the same stock accompanies the component through treatment cycles such as hardening or coating.

Arbor

(1) In machine grinding, the spindle on which the wheel is mounted. (2) In machine cutting, a shaft or bar for holding and driving the cutter. (3) In foundry, a metal shape embedded in green sand or dry sand cores to support the sand or the applied load during casting.

Arbor Press

A machine used for forcing arbors or mandrels into drilled or bored parts preparatory to turning or grinding. Also used for forcing bushings, shafts, or pins into or out of holes.

Arborescent Powder

See preferred term *dendritic powder*.

Arbor-Type Cutter

A cutter having a hole for mounting on an arbor and usually having a keyway for a driving key.

Arc

The passage of an electrical current across the gap between two electrodes in vacuum, air, or liquid. The electrical transfer is accompanied by radiation of heat and light.

Arc Air Cutting/Gouging

Processes in which an electric arc melts the material, which is then ejected by at high velocity air stream. The arc may be struck between the component and electrode or between two electrodes. In welding, the undesirable deflection of the electric arc by magnetic fields usually arising from the welding currents.

Arc Blow

The deflection of an electric arc from its normal path because of magnetic forces.

Arc Brazing

A brazing process in which the heat required is obtained from an electric arc struck between two nonconsumable electrodes. See *twin carbon arc brazing*.

Arc Chamber

The confined space enclosing the anode and cathode in which the arc is struck.

Arc Cutting

A group of cutting processes that melts the metals to be cut with the heat of an arc between an electrode and the base metal. See *carbon arc cutting*, *metal arc cutting*, *gas metal arc cutting*, *gas tungsten arc cutting*, *plasma arc cutting*, and *air carbon arc cutting*. Compare with *oxygen arc cutting* and *arc air cutting*.

Arc Discharge

Arc discharge is a type of electrical conduction in gases characterized by high current density and low potential drop. A typical arc runs at a voltage drop of 100 V with a current drain of 10 A. The arc has negative resistance—the voltage drop decreases as the current increases—so a stabilizing resistor or inductor in series is required to maintain it. The high-temperature gas rises like a hot-air balloon, while it remains anchored to the current-feeding electrodes at its ends. It thereby acquires an upward-curving shape, which accounts for it being called an arc.

There are many applications of such an intensely hot object. The brilliant arc and the incandescent carbon adjacent to it form the standard light source for movie theater projectors. The electronic flash gun in a camera uses an intense pulsed arc in xenon gas, simulating sunlight. Since no solid-state material can withstand this temperature for long, the arc is used industrially for welding steel and other metals. Alternatively, it can be used for cutting metal very rapidly. Electric arcs form automatically when the contacts in electrical switches and power networks are opened, and much effort goes into controlling and extinguishing them. Lightning is an example of a naturally occurring electric arc.

Arc Force

The axial force developed by a plasma.

Arc Furnace

A furnace in which metal is melted either directly by an electric arc between the electrode and the work or indirectly by an arc between two electrodes adjacent to the metal.

Arc Gas

The gas introduced into the arc chamber and ionized by the arc to form a plasma.

Arc Gouging

An arc cutting process variation used to form a bevel or groove.

Arc Melting

Melting of a material by an electrical arc. The term normally refers to melting in a furnace rather than in processes such as arc welding.

Arc of Contact

The portion of the circumference of a grinding wheel or cutter touching the work being processed.

Arc Oxygen Cutting

See preferred term *oxygen arc cutting*.

Arc Plasma

See *plasma*.

Arc Plasma Welding

Same as *plasma arc welding*.

Arc Resistance

Ability to withstand exposure to an electric voltage. The total time in seconds that an intermittent arc may play across a plastic surface without rendering the surface conductive.

Arc Seam Weld

A seam weld made by an arc welding process.

Arc Spot Weld

A spot weld made by an arc welding process.

Arc Strike

A discontinuity consisting of any localized remelted metal, heat-affected metal, or change in the surface profile of any part of a weld or base metal resulting from an arc. In welding, the unintentional striking of an arc on parent material or previously deposited weld and the damage caused thereby. Such damage may range from superficial blemishes to serious cracking.

Arc Time

The time an arc is maintained in making an arc weld. Also known as *weld time*.

Arc Voltage

The voltage across the welding arc.

Arc Welding

A group of welding processes that produces coalescence of metals by heating them with arc, with or without the application of pressure and with or without the use of filler metal. See *electric arc welding*.

Arc Welding Electrode

A component of the welding circuit through which current is conducted between the electrode holder and the arc. See *arc welding*.

Arc Welding Gun

A device used in semiautomatic, machine, and automatic arc welding to transfer current, guide the consumable electrode, and direct shielding gas when used.

Ar_{cm} , Ar_1 , Ar_3 , Ar_4 , Ar' , Ar''

Defined under *transformation temperature*.

Area of Contact

A general term that, without other modifying terminology, is insufficiently specific to be defined precisely. Its use should therefore be avoided. Related terms are *actual area of contact*, *apparent area of contact*, *Hertzian contact area*, *nominal area of contact*, and *real area of contact*.

Areal Weight

The weight of a fiber reinforcement per unit area (width $\times$ length) of tape or fabric.

Argon

A chemical element (symbol Ar); Argon is the third member of the gaseous elements called a noble, inert, or rare gas, although argon is not actually rare. The earth's atmosphere is the only commercial argon source; however, traces of the gas are found in minerals and meteorites.

Argon is a colorless, odorless, and tasteless gas. The element is a gas under ordinary conditions, but it can be liquefied, solidified readily, and is a major industrial gas.

Argon does not form any chemical compounds in the ordinary sense of the word, although it does form some weakly bonded compounds with water, hydroquinone, and phenol. There is one atom in each molecule of gaseous argon.

Most argon is produced in air-separation plants. Air is liquefied and subjected to fractional distillation. Because the boiling point of argon is between that of N_2 and O_2 , an argon-rich mixture can be taken from a tray near the center of the upper distillation column. The argon-rich mixture is further distilled and then warmed and catalytically burned with H_2 to remove O_2 . A final distillation removes H_2 and N_2 , yielding a very high purity.

The oldest largest-scale use for argon is in filling electric light bulbs. Welding and cutting metal consumes the largest amount of argon. Metallurgical processing constitutes an important application.

Argon and Ar-Kr mixtures are used, along with a little mercury vapor, to fill fluorescent lamps. The inert gases make the lamps easier to start, help to regulate the voltage, and supplement the radiation produced by the excited mercury vapor.

Argon mixed with a little neon is used to fill luminous electric-discharge tubes employed in advertising signs (similar to neon signs) when a blue or green color is desired instead of the red color of neon.

Argon is used to fill the space between the panes of higher-quality double-pane windows, reducing heat transfer by gaseous conduction by about 30% compared to air filling.

A

Argon is also used in gas-filled thyratrons. Geiger–Müller radiation counters, and electron tubes of various kinds. Argon atmospheres are used in dry boxes during manipulation of very reactive chemicals in the laboratory and in sealed-package shipments of such materials. In high-energy physics research, a tank of liquid argon can form a calorimeter to detect certain subatomic particles.

Argon Arc Welding

Electric arc welding in which the weld zone is protected by a shroud of argon gas.

Argon Oxygen Decarbonization

A secondary refining process for the controlled oxidation of carbon in a steel melt. In the argon oxygen decarbonization process, oxygen, argon, and nitrogen are injected into a molten metal bath through submerged, side-mounted tuyeres.

Argonaut Welding

A proprietary form of metal inert gas welding.

Arm (Resistance Welding)

A projecting beam extending from the frame of a resistance welding machine that transmits the electrode force and may conduct the welding current.

Armco Iron

A proprietary grade of commercially pure iron with low hardness, high ductility, and good corrosion resistance compared with carbon steel.

Armor Plate

An imprecise term usually indicating steel with a strength of about 1000 MPa. It may be through hardened, face hardened, or carburized on one face or composite, that is, in multilayer form. The term is also applied to nonferrous materials such as higher strength aluminum alloys when these are used as the skin of armored vehicles.

Aromatic Hydrocarbon

A hydrocarbon with a chemistry similar to that of benzene. Aromatic hydrocarbons are either benzenoid or nonbenzenoid. Benzenoid aromatic hydrocarbons contain one or more benzene rings and are by far the more common and the more important commercially. Nonbenzenoid aromatic hydrocarbons have carbon rings that are either smaller or larger than the six-membered benzene ring. Their importance arises mainly from a theoretical interest in understanding those structural features that imparts the property of aromaticity. Benzenoid aromatic hydrocarbons are also called arenes. Benzene itself is the prototypical arene.

Aromatic Polyester

A polyester derived from monomers in which all the hydroxyl and carboxyl groups are directly linked to aromatic nuclei.

Arrest Line (Ceramics)

Rib mark defining the crack front shape of an arrested crack prior to resumption of crack spread under an altered stress configuration. The duration of rest may be long to infinitesimal. See also *rib mark*.

Arrest Marks

Concentric marks on the surface of a fatigue fracture. They are visible to the unaided eye and mark the crack front at irregularities in the load cycling such as interruptions in cycling or an abnormal load. Also termed chonchoidal marks, shell marks, or beach marks. Compare with striations.

Arrest Points

The inflections observed on the curves plotted in the thermal analysis of metals and alloys. They reflect changes in the rate of heat release or absorption and hence identify the location of phase changes.

Arrhenius Equation

A semiempirical formula applicable to many rate control processes such as diffusion, some stages of creep, and some corrosion processes. It is usually presented as

$$\text{Rate} = Ae^{-E_a/RT}$$

where

A is the Arrhenius constant
 E_a is the activation energy
 R is Boltzmann's constant
 T is temperature absolute

Arsenic

Arsenic (symbol As) is a soft, brittle, poisonous element of steel-gray color and metallic luster. In atomic structure, it is a semimetal, lacking plasticity, and is used only in alloys and compounds. The bulk of the arsenic used is employed in insecticides, rat poisons, and weed killers, but it has many industrial uses, especially in pigments. It is also used in poison gases for chemical warfare.

Metallic arsenic is stable in dry air. When exposed to human or moistened air, the surface first becomes coated with a superficial golden bronze tarnish, which on further exposure turns black. On heating in air, arsenic will vaporize and burn to As_2O_3 .

Dermatitis can result from handling arsenical compounds; hence, it is desirable to use impervious gloves or protective creams. The best preventative for dermatitis is strict personal hygiene. In areas where arsenical dust and fumes are present, effective exhaust ventilation is necessary, or when impractical, a respirator should be used.

In the field of electronics, high-purity arsenic is finding an important use as a constituent of the III–V semiconductor compounds. The compounds of most interest are indium arsenide, which may be used for Hall effect devices, and gallium arsenide used for making diodes, transistors, and solar cells.

Arsenic has little commercial application in the pure form, but as an alloying element, it improves oxidation resistance and high-temperature strength in copper, inhibits dezincification in some brass, and hardens lead.

Arsenical Copper

Copper with up to 0.5% arsenic to improve high-temperature properties including creep strength and enhanced resistance to atmospheric oxidation.

Artifact

Generally, a manmade as opposed to a naturally occurring structure. And its metallurgical sense of feature not arising naturally in the material or microstructure in question, for example, an inadvertent scratch or a piece of dust on a metallographic specimen that could be mistaken for a structural feature or erroneously interpreted as a real feature. See also *abrasion artifact*, *mounting artifact*, and *polishing artifact*.

Artificial Aging (Heat Treatment)

Aging above room temperature. See *aging (heat treatment)*. Compare with *natural aging*.

Artificial Aging (Plastics)

The exposure of a plastic to conditions that accelerate the effects of time. Such conditions include heating, exposure to cold, flexing, application of electric field, exposure to chemicals, ultraviolet light radiation, and so forth. Typically, the conditions chosen for such testing reflect the conditions under which the plastic article will be used. Usually, the length of time the article is exposed to these test conditions is relatively short. Properties such as dimensional stability, mechanical fatigue, chemical resistance, stress cracking resistance, dielectric strength, and so forth, are evaluated in such testing. See also *aging*.

Artificial Intelligence

Artificial intelligence is the subfield of computer science concerned with understanding the nature of intelligence and constructing computer systems capable of intelligent action, abbreviated AI. It embodies the dual means of furthering basic scientific understanding and of making computers more sophisticated in the service of humanity.

AI is primarily concerned with symbolic representations of knowledge and heuristic methods of reasoning, that is, using common assumptions and rules of thumb. Two examples of problems studied in AI are planning how a robot, or person, might assemble a complicated device or move from one place to another and diagnosing the nature of a person's disease, or of a machine's malfunction, from the observable manifestations of the problem. In both cases, reasoning with symbolic descriptions predominates over calculating.

Artificial Weathering

The exposure of plastics to cyclic laboratory conditions, consisting of low temperatures, high and low relative humidities, and ultraviolet radiation energy, with or without direct water spray and moving air (wind), in an attempt to produce changes in the properties of the plastics similar to those observed after long-term continuous exposure outdoors. The laboratory exposure conditions are usually more intensified than those encountered in actual outdoor exposure in an attempt to achieve an accelerated effect. Also called accelerated aging.

Artificially Layered Structures

Manufactured, reproducibly layered structures with layer thicknesses approaching interatomic distances. Modern thin-film techniques are at a stage at which it is possible to fabricate these structures, also known as artificial crystals or superlattices, opening up the possibility of engineering new desirable properties into materials.

These structures serve as model systems and as a testing ground for theoretical models and for other naturally occurring materials that have similar structures. For example, ceramic superconductors consist of a variable number of conducting CuO_2 layers intercalated by various other oxide layers, and therefore, artificially layered structures may be used to study predictions of the behavior of suitably manufactured materials of this class.

Asbestos

Any of six naturally occurring minerals characterized by being extremely fibrous (asbestiform), strong, and incombustible. They are utilized in commerce for fire protection; as reinforcing material for tiles, plastics, and cements; for friction materials; and for thousands of other uses. Because of a great concern over the health effects of asbestos, many countries have promulgated strict regulations for its use. The six minerals designated as asbestos also occur in a nonfibrous form. In addition, there are many other minerals that morphologically mimic asbestos because of their fibrous nature.

The six naturally occurring minerals exploited commercially for their desirable physical properties, which are in part derived from their asbestiform habit, are chrysotile asbestos, a member of the serpentine mineral group, and grunerite asbestos, riebeckite asbestos, anthophyllite asbestos, tremolite asbestos, and actinolite asbestos, all members of the amphibole mineral group. Individual mineral particles, however, processed and regardless of their mineral name, are not demonstrated to be asbestos is the average length-to-width ratio which is less than 20:1.

Chrysotile is a hydrated magnesium silicate from the serpentine mineral group. Amosite and ercidolite are iron silicates from the amphibole mineral group. Anthophyllite is a magnesium silicate of the amphibole group with the magnesium isomorphically replaced by varying amounts of iron and aluminum.

The important characteristics of the asbestos minerals that make them unique are their fibrous form; high-strength and surface area; resistance to heat, acids, moisture, and weathering; and good bonding characteristics with most binders such as resins and cement.

Asbestos is used for many types of products because of its chemical and thermal stability, high tensile strength, flexibility, low electrical conductivity, and large surface area. Past uses of asbestos, such as sprayed-on insulation, where the fibers may become easily airborne, have been generally abandoned. Asbestos is used predominantly for the construction industry in the form of cement sheets, coatings, pipes, and roofing products. Additional important uses are for reinforcing plastics and tiles, for friction materials, and packings and gaskets.

- *Asbestos fabrics* are often a woven mix with some cotton. For brake linings and clutch facings, the asbestos is woven with fine metallic wire.
- *Asbestos shingles*, for fireproof roofing and siding of houses, are normally made of asbestos fibers and Portland cement forms on hydraulic pressure.

A

- *Asbestos board* is a construction or insulating material in sheets made of asbestos fibers and Portland cement molded under hydraulic pressure. Ordinary board for the siding and partitions of warehouses and utility buildings is in the natural mottled-gray color, but pigmented boards are also marketed in various colors.
- *Asbestos lumber* is asbestos–cement board molded in the form of boards for flooring and partitions, usually with imitation wood grain molded into the surface. Asbestos siding, for house construction, is grained to imitate cypress or other wood and is pigmented with titanium oxide to give a clear white color. Asbestos roofing materials may also be made with asphalt or other binder instead of cement.
- Asbestos paper is a thin asbestos sheeting made of asbestos fibers bonded usually with a solution of sodium silicate. It is strong, flexible, and white in color and is fireproof and a good heat insulator. For covering steam pipes and for insulating walls, it is made in sheets of two or three plies. For wall insulation, it is also made double with one-corrugated sheet to form air pockets when in place.

Other applications include insulating cements, fireproof garments, curtains, shields, brake linings, pipe coverings, and molded products.

Asbestos also appears granular, in crystals, compact such as nephrite, which is the jade of the Orient. Jade appears as a solid rock and is highly valued for making ornamental objects.

As-Brazed

The condition of brazements after brazing, prior to any subsequent thermal, mechanical, or chemical treatments.

As-Cast Condition

Castings as removed from the mold without subsequent heat treatment.

As-Cast/As-Welded

The condition reached upon completion of the indicated process but prior to heat treatment or other processing.

Ash Content

Proportion of the solid residue remaining after a reinforcing substance has been incinerated (charred or intensely heated).

Aspect Ratio

Depending upon context, various ratios such as length to diameter (fibers), lanes to width (crack), depth to diameter (corrosion pit), etc.

Asphalt

Asphalt refers to varieties of naturally occurring bitumen. Acetyl was also produced as a petroleum byproduct. Those substances are black and largely soluble in carbon disulfide. Asphalt are of variable consistency, ranging from a highly viscous fluid to a solid.

Asphalt is derived from petroleum in commercial quantities by removal of volatile components. It is an inexpensive construction material used primarily as a cementing and waterproofing agent.

Asphalt is composed of hydrocarbons and heterocyclic compounds containing N₂, sulfur, O₂; its components vary in molecular weight from about 400 to 5000. It is thermoplastic and viscoelastic; at high temperatures or over long loading times, it behaves as a viscous fluid; at low temperatures or short loading times as an elastic body.

The three distinct types of asphalt made from petroleum residues and their uses are described in Table A.15.

A-Spot

One of many small contact areas through which electrical current can pass when two rough, conductive solid surfaces are touching.

Assay

Determination of how much of a sample is the material indicated by the name. For example, foreign assay of FeSO₄ the analysis would determine both iron and SO₄²⁻ in the sample.

Assay Value

The measure of the metal content of an ore of precious metal. It may be expressed as a weight percentage or, traditionally, as troy ounces of metal per avoirdupois ton of ore.

TABLE A.15
Asphalts and Their Uses

Asphalt Type and % of Production	Manufacturing Process	Properties	Uses
Straight-run, 70%–75%	Distillation or solvent precipitation	Nearly viscous flow	Roads, airport runways, hydraulic works
Air-blown, 25%–30%	Reacting with air at 204°C–316°C	Resilient: viscosity less susceptible to temperature change than straight-run	Roofing, pipe coating, paints, underbody coatings, paper laminates
Cracked, less than 5%	Heating to 427°C–538°C	Nearly viscous flow; viscosity more susceptible to temperature change than that of straight-run asphalt	Insulation board saturant, dust laying

Source: McGraw-Hill Encyclopedia of Science and Technology, 8th edn., Vol. 2, McGraw-Hill, New York, p. 176. With permission.

Assembly

A number of parts or subassemblies or any combination thereof joined together.

Assembly Adhesive

An adhesive that can be used for bonding parts together, such as in the manufacture of a boat, an airplane, furniture, and the like. The term assembly adhesive is commonly used in the wood industry to distinguish such adhesives (formally called joint glues) from those used in making plywood (sometimes called veneer glues). It describes adhesive used in fabricating finished structures or goods, or subassemblies thereof, as differentiated from adhesives used in the production of sheet materials for sale as such, for example, plywood or laminates.

Assembly Line (Adhesives)

The time interval between the spreading of the adhesive on the adherend and the application of pressure or heat, or both, to the assembly. For some ways involving multiple layers or parts, the assembly time begins with the spreading of the adhesive on the first adherend. See also *closed assembly time* and *open assembly time*.

A-Stage

An early stage in the reaction of certain thermosetting resins in which the material is fusible and still soluble in certain liquids. Synonym for *resole*. Compare with *B-stage* and *C-stage*.

Astigmatism

A defect in a lens or optical system that causes rays in one plane parallel to the optical axis to focus at a distance different from those in the plane at right angles to it.

As-Welded

The condition of weld metal, welded joints, and weldments after welding but prior to any subsequent thermal, mechanical, or chemical treatments.

Atactic Stereoisomerism

A chain of molecules in which the position of the side chains or side atoms is more or less random. See also *isotactic stereoisomerism* and *syndiotactic stereoisomerism*.

Athermal

Not isothermal. Changing rather than constant temperature conditions.

Athermal Transformation

A reaction that proceeds without benefit of thermal fluctuations—that is, thermal activation is not required. Such reactions are diffusionless and can take place with great speed when the driving force is sufficiently high. For example, many martensitic transformations occur athermally on cooling, even at relatively low temperatures,

because of the progressively increasing drive force. In contrast, a reaction that occurs at constant temperature is an *isothermal transformation*; thermal activation is necessary in this case and the reaction proceeds as a function of time.

Atmospheric Corrosion

The gradual degradation or alteration of a material by contact with substances present in the atmosphere, such as oxygen, carbon dioxide, water vapor, and sulfur and chlorine compounds.

Atmospheric Riser

A riser that uses atmospheric pressure to aid feeding. Essentially, a *blind riser* into which a small core or rod protrudes; the functions of the core or rod is to provide an open passage so that the molten interior of the riser will not be under a partial vacuum when metal is withdrawn to feed the casting but will always be under atmospheric pressure.

Atom

The smallest particle of an element that retains the characteristic properties and behavior of the element. Further division of the atom, termed fission or, colloquially, splitting the atom, reduces it to its constituent, subatomic, particles: protons, electrons, neutrons, etc. See also *atomic structure*, *isotope*, and *nuclear structure*.

Atom Probe

An instrument for measuring the mass of a single atom or molecule on a metal surface; it consists of a field ion microscope with a hole in its screen opening into a mass spectrometer; atoms are removed from the specimen by pulsed field evaporation, travel through the hole, and are detected in the mass spectrometer. See also *field-ion microscopy*.

Atomic Absorption Spectrometry

The measurement of light absorbed at the wavelength of resonance lines by the unexcited atoms of an element.

Atomic Arrangement

The way atoms are arranged in a crystal structure.

Atomic Fission

The breakup of the nucleus of an atom in which the combined weight of the fragments is less than that of the original nucleus, the difference being converted to a very large energy release.

Atomic Hydrogen

Hydrogen in a state in which the atoms are not bonded to each other. Normally hydrogen atoms bond strongly together in pairs to form molecules. If the hydrogen molecule, H_2 , is raised to a high energy level by heating, it disassociates into two individual H atoms. When the atoms recombine, a large amount of heat is released.

A

Atomic Hydrogen (Welding) Process

An arc welding process that fuses metals together by heating them with an electric arc maintained between two metal electrodes enveloped in a stream of hydrogen. Shielding is provided by the hydrogen, which also carries heat by molecular disassociation and subsequent recombination. Pressure may or may not be used and filler metal may or may not be used. (This process is now of limited industrial significance.)

Atomic Mass

The mass of one atom of an element relative to the mass of a reference element. Originally, the reference element was hydrogen, atomic mass of 1.0, then oxygen of atomic mass 16.0, or carbon of atomic mass 12. See also *atomic weight*.

Atomic Number (Z)

The number of elementary positive charges (protons) contained within the nucleus of an atom. For an electrically neutral atom, the number of planetary electrons is also given by the atomic number. Atoms with the same Z (isotopes) may contain different numbers of neutrons. Also known as nuclear charge. See also *isotope* and *proton*.

Atomic Number Contrast

See *atomic number imaging*.

Atomic Number Imaging

In scanning electron microscopy, a technique in which contrast is controlled by atomic number (high atomic number areas appear light, while low atomic number areas appear dark). Usually obtained by imaging based on backscattered electron signal. See also *backscattered electron*.

Atomic Percentage

The composition of an alloy or mixture in terms of the number of atoms of each constituent for hundreds of mixture.

Atomic Replica

A thin replica devoid of structure on the molecular level. It is prepared by the vacuum or hydrolytic deposition of metals or simple compounds of low molecular weight. See also *replica*.

Atomic Scattering Factor, f

The ratio of the amplitude of the wave scattered by an atom to that scattered by a single electron.

Atomic Structure

The arrangement of the parts of an atom, which consists of a positively charged nucleus surrounded by a cloud of electrons arranged in orbits that can be described in terms of quantum mechanics.

Atomic Weight

(1) A number assigned to each chemical element that specifies the average mass of its atoms. Because an element may consist of two or more isotopes, each having atoms with well-defined but differing masses, the atomic weight of each element is the average of the masses of its naturally occurring isotopes weighted by the relative proportions of those isotopes. (2) The mean weight of the atom of an element in relation to $^{12}\text{C} = 12.000$.

Atomization (Materials Characterization)

The subdivision of a compound into individual atoms using heat or chemical reactions. This is a necessary step in atomic spectroscopy. See also *atomizer* and *nebulizer*.

Atomization (Powder Metallurgy)

The disintegration of a molten metal into particles by a rapidly moving gas or liquid stream or by other means.

Atomization (Thermal Spraying)

The division of molten material at the end of the wire or rod into fine particles.

Atomizer

A device that atomizes a sample, for example, a burner, plasma, or hydride reaction chamber. See also *atomization* and *nebulizer*.

Attack Polishing

Simultaneous etching and mechanical polishing.

Attenuation

(1) The fractional decrease of the intensity of energy flux, including the reduction of intensity resulting from geometrical spreading, absorption, and scattering. (2) The diminution of vibrations or energy over time or distance. The process of making thin and slender, as applied to the formation of fiber from molten glass. (3) The exponential decrease with distance in the amplitude of an electrical signal traveling along a very long, uniform transmission line, due to conductor and dielectric losses.

Attitude (Attitude Angle)

In a bearing, the angular position of the line joining the center of the journal to that of the bearing bore, relative to the direction of loading.

Attrition

Removal of small fragments of surface material during sliding contact.

Attritious Wear

Wear of abrasive grains in grinding such that the sharp edges gradually become rounded. A grinding wheel that has undergone such wear usually has a glazed appearance.

Attritor

A high-intensity ball mill whose drum is stationary and whose balls are agitated by rotating baffles, paddles, or rods at right angle to the drum axis.

Attritor Grinding

The intensive grinding or alloying in an attritor. Examples are milling of carbides and binder metal powders and mechanical alloying of hard dispersoid particles with softer metal or alloy powders. See also *mechanical alloying*.

Auger Chemical Shift

The displacement and energy of an Auger electron peak for an element due to a change in chemical bonding relative to a specified element or compound.

Auger Electron

An electron emitted from an atom with a vacancy and an inner shell. Auger electrons have a characteristic energy detected as peaks in the energy spectra of the secondary electrons generated.

Auger Electron Spectroscopy

A technique for chemical analysis of surface layers that identifies the atoms present in a layer by measuring the characteristic energies of their Auger electrons.

Auger Electron Yield

The probability that an atom with a vacancy in a particular inner shell will relax by an Auger process.

Auger Map

A 2D image of the specimen surface showing the location of emission of Auger electrons from a particular element. A map is normally produced by rastering the incident electron beam over the specimen surface and simultaneously recording the Auger signal strength for a particular transition as a function of position.

Auger Matrix Effects

Effects that cause changes in the shape of an Auger electron energy distribution or in the Auger signal strength for an element due to the physical environment of the emitting atom and not due to bonding with other elements or changes in concentration.

Auger Process

The radiationless relaxation of an atom, involving a vacancy and then enters the electron shell. An electron (known as an Auger electron) is emitted.

Auger Transition Designations

Transitions are designated by the electron shells involved. The first letter designates the shell containing the initial vacancy; the last two

letters designate the shelves containing electron vacancies created by Auger emission (e.g., KLL and LMN).

Ausforming

Mechanical working of a suitable steel that has been rapidly cooled to retain the austenitic phase below the lower critical temperature, 723°C in carbon steels. It is implicit that the steel composition is such that the austenite is unstable below this temperature and it will eventually transform to martensite or bainite. Such treatment, which effectively combines hardening by working with hardening by transformation can produce very high-strength components. See *steel* and *isothermal transformation*. Note that the term is not appropriate for steels that will remain austenitic.

Austempered Ductile Iron

A moderately alloyed *ductile iron* that is austempered for high strength with appreciable ductility. See also *austempering*.

Austempering

A heat treatment for ferrous alloys in which a part is quenched from the austenitizing temperature at a rate fast enough to avoid formation of ferrite or pearlite and then held at a temperature just above M_s until transformation to bainite is complete. Also designated as bainite in both austempered steel and austempered ductile iron, austempered steel consists of two phase mixtures containing ferrite and carbide, while austempered ductile iron consists of two phase mixtures containing ferrite and austenite.

Austenite

A solid solution of one or more elements interface-centered cubic iron (gamma iron). Unless otherwise designated (such as nickel austenite), the solute is generally assumed to be carbon.

Austenitic Corrosion-Resistant Stainless Steel

A highly alloyed corrosion-resistant stainless steel containing 16% or more chromium, a ferrite-stabilizing element, and sufficient austenite-stabilizing elements such as nickel (up to about 35%), manganese, and nitrogen. See also *stainless steels*.

Austenitic Grain Size

Generally, the grain size of steel when in the austenitic state. The term is also used in the sense of an inherent austenitic grain size, established by the original steelmaking practice, which influences the steel properties even after a number of subsequent working and heat treatment operations. This may be revealed by appropriate etching of cross sections after cooling to room temperature. The term "prior austenitic grain size" usually refers to the grain size when the steel was last in the austenitic condition.

Austenitic Manganese Steel

A cast, wear-resistant material containing about 1.2% C and 12% Mn. This usually implies a high content of nickel or manganese. The steel will be nonmagnetic but will be "stainless" only if it contains more than 12% chromium. Used primarily in the fields of earth

A

moving, mining, quarrying, railroading, ore processing, lumbering, and in the manufacture of cement and clay products. Also known as Hadfield steel.

Austenitic Steel

An alloy steel whose structure is normally austenitic at room temperature.

Austenitizing

Forming austenite by heating a ferrous alloy into the transformation range (partial austenitizing) or above the transformation range (complete austenitizing). When used without qualification, the term implies complete austenitizing.

Autoclave

A close vessel for conducting and completing either a chemical reaction under pressure and heat or other operation, such as cooling. Widely used for bonding and curing reinforced plastic laminates.

Autoclave Molding

A process in which, after lay-up, winding, or wrapping, an entire assembly is placed in a heated autoclave, usually at 340–1380 kPa (50–200 psi). Additional pressure permits higher density and improved removal of volatiles from the resin. Lay-up is usually vacuum bagged with a bleeder and release cloth.

Autofrettage

Prestressing a hollow metal cylinder by the use of momentary internal pressure exceeding the yield strength.

Autogenous Weld

A weld made by the fusion of the parent components without the addition of filler metal.

Automated Image Analysis

See *image analysis*.

Automatic Brazing

Brazing with equipment that performs the brazing operation without constant observation and adjustment by a brazing operator. The equipment may or may not perform the loading and unloading of the work. See also *machine brazing*.

Automatic Gas Cutting

See preferred term *automatic oxygen cutting*.

Automatic Mold

A mold for injection or compression molding of plastics that repeatedly goes through the entire cycle, including ejection, without human assistance.

Automatic Oxygen Cutting

Oxygen cutting with equipment that performs the cutting operation without constant observation and adjustment of the controls by an operator. The equipment may or may not perform loading and unloading of the work. See also *machine oxygen cutting*.

Automatic Press (Metals)

A press in which the work is fed mechanically through the press in synchronism with the press action. An automation press is an automatic press that, in addition, is provided with built-in electrical and pneumatic control equipment.

Automatic Press (Plastics)

A hydraulic press for compression molding or an injection machine that operates continuously, being controlled mechanically (toggle) or hydraulically, or by a combination of these methods.

Automatic Press Stop

A machine-generated signal for stopping the action of a press, usually after a complete cycle, by disengaging the clutch mechanism and engaging the brake mechanism.

Automatic Welding

Welding with equipment that performs the welding operation without adjustment of the controls by a welding operator. The equipment may or may not perform the loading and unloading of the work. See also *machine welding*.

Automation Press

See *automatic press*.

Autoradiography

An inspection technique in which radiation spontaneously emitted by a material is recorded photographically. The radiation is emitted by radioisotopes that are (1) produced in a metal by bombarding it with neutrons, (2) added to a metal such as by alloying, or (3) contained within a cavity in a metal part. The technique serves to locate the position of the radioactive element or compound.

Auxiliary Anode

In electroplating, a supplementary *anode* positioned so as to raise the current density on a certain area of the *cathode* and thus obtain better distribution of plating.

Auxiliary Electrode

An *electrode* commonly used in polarization studies to pass current to or from a test electrode. It is usually made from a noncorroding material.

Auxiliary Magnifier or Enlarger (Eye Protection)

An additional lens or plate, associated with eye protection equipment, used to magnify or enlarge the field of vision.

Average Density

The density measured on an entire body or on a major number of its parts whose measurements are then averaged.

Average Erosion Rate

The cumulative erosion divided by the corresponding cumulative exposure duration, that is, the slope of a line from the origin to a specified point on the cumulative erosion-time curve.

Average Grain Diameter

The mean diameter of an equiaxed grain section whose size represents all the grain sections in the aggregate being measured. See also *grain size*.

Average Linear Strain

See *engineering strain*.

Average Molecular Weight

The molecular weight of the most typical chain in a given plastic; it is characteristic of neither the longest nor the shortest chain.

Average Particle Size

A single value representing the entire particle size distribution.

Avogadro's Number

The number of molecules (6.02×10^{23}) in a gram molecular weight of any substance. See also *gram molecular weight* and *mole*.

Axial

Longitudinal or parallel to the axis or center line of a part. Usually refers to axial compression or axial tension.

Axial Load Bearing

See *thrust bearing*.

Axial Relief

The relief for clearance behind the end cutting edge of a milling cutter. See also *face mill*.

Axial Rolls

And *ring rolling*, vertically displaceable, tape rolls mounted in a horizontally displaceable frame opposite to, but on the same center-line as, the main roll and rolling mandrel. The actual rolls control ring height during rolling.

Axial Winding

In filament-wound reinforced plastics, a winding with the filament parallel to, or at a small angle to, the axis (0° helix angle). See also *polar winding*.

Axis (Crystal)

The edge of the unit cell of a space lattice. Any one axis of any one lattice is defined in length and direction relative to other axes of that lattice.

Taylor & Francis

Taylor & Francis Group

<http://taylorandfrancis.com>

B

The symbol for a repeating unit in a copolymer chain.

Babbitt Metal

The original name for tin–antimony–copper (Sn–Sb–Cu) white alloys used for machinery bearings; the term now applies to almost any white bearing alloy with either tin or lead base. The alloy consists of 88.9% tin, 7.4% antimony, and 3.7% copper. This alloy melts at 239°C. It has a Brinell hardness of 35 at 21°C and 15 at 100°C. As a general-utility-bearing metal, the original alloy has never been improved greatly, and makers frequently designate the tin-base alloys close to this composition as genuine babbitt.

Commercial white bearing metals now known as babbitt are of three general classes: tin-base, with more than 50% tin hardened with antimony and copper and used for heavy-duty service; intermediate, with 20%–50% tin, with lower compressive strength and more sluggish behavior as a bearing; and lead-base, made usually with antimonial lead with smaller amounts of tin together with other elements to hold the lead in solution.

Copper hardens and toughens the alloy and raises the melting point. Lead increases fluidity and raises antifriction qualities but softens the alloy and decreases its compressive strength. Antimony hardens the metal and forms hard crystals in a soft matrix, which improves the alloy as a bearing metal.

Alloys containing up to 1% arsenic (As) are harder at high temperatures and are fine-grained, but arsenic is used chiefly for holding lead in suspension. Zinc (Zn) increases hardness but decreases frictional qualities, and with much zinc the bearings are inclined to stick. Even minute quantities of iron (Fe) harden the alloys, and iron is not used except when zinc is present. Bismuth (Bi) reduces shrinkage and refines the grain but lowers the melting point and the strength at elevated temperatures. Cadmium (Cd) increases the strength and fatigue resistance, but any considerable amount lowers the frictional qualities, lowers the strength at higher temperatures, and causes corrosion. Nickel (Ni) is used to increase strength and raises the melting point. The normal amount of copper in babbitts is 3%–4%, at which point the maximum fatigue-resisting properties are obtained with about 7% antimony. More than 4% copper tends to weaken the alloy and raises the melting point. When the copper is very high, tin–copper crystals are formed and the alloy is more a bronze than a babbitt.

Because of the increased speeds and pressures in bearings and the trend to lighter weights, heavy-cast babbitt bearings are now little used despite their low cost and the ease of casting the alloys. The alloys are used mostly as antifriction metals in thin facings on steel backings, with the facing usually less than 0.03 cm thick, in order to increase their ability to sustain higher loads and dissipate heat.

Back Bead

See preferred term *back weld*.

Back Draft

A reverse taper on a casting pattern or a forging die that prevents the pattern or forged stock from being removed from the cavity.

Back Extrusion

See *backward extrusion*.

Back Gouging

The removal of weld metal and base metal from the other side of a partially welded joint to ensure complete penetration upon subsequent welding from that side.

Back Pressure

Resistance of a plastic, because of its viscosity, to continued flow when the mold is closing.

Back Rake

The angle on a single-point turning tool corresponding to axial rake in milling. It is the angle measured between the plane of the tool face and the reference plane and lies in a plane perpendicular to the axis of the work material and a base of the tool. See *single-point tool*.

Back Reflection

The diffraction of x-rays at a *Bragg angle* approaching 90°.

Back Reflection X-Ray Technique

A technique for studying the crystal structure in which a narrow, collimated beam of monochromatic x-rays is directed at the metal through a hole in a photographic film. *Crystallographic planes in the crystal structure reflect x-rays back onto the film producing dot patterns that can be interpreted to indicate grain size, cold work, etc. Sometimes termed von Laue analysis after the pioneer in such work.*

Back Side

The side of a plastic or composite part that is cured against the vacuum bag.

Back Step Sequence

A longitudinal sequence in which the weld bead increments are deposited in the direction opposite to the progress of welding the joint. See also *block sequence*, *cascade sequence*, *continuous sequence*, *joint building sequence*, and *longitudinal sequence*.

B

Back Taper

Reverse draft used in a mold to prevent the molded plastic article from drawing freely. See also *undercut*.

Back Weld

A weld deposited at the back of a single groove weld.

Backfill

Material placed in a drilled hole to fill space around anodes, vent pipe, and buried components of a cathodic protection system.

Backfire

The momentary recession of the flame into the welding tip or cutting tip followed by immediate reappearance or complete extinction of the flame. See also *flashback*.

Background

Any noise in the signal due to instabilities in the system or to environmental interferences. See also *signal-to-noise ratio*.

Backhand Welding

The welding technique in which the welding torch or gun is directed opposite to the progress of welding. Sometimes referred to as the “pull gun technique” in gas metal arc welding and flux-cored arc welding. Compare with *forehand welding*. See also *travel angle*, *work angle*, and *drag angle*.

Backing

(1) In grinding, the material (paper, cloth, or fiber) that serves as the base for coated abrasives. (2) In welding, a material placed under or behind a joint to enhance the quality of the weld at the root. It may be a metal backing ring or strip, a pass of weld metal, or a nonmetal such as carbon, granular flux, or a protective gas. (3) In plain bearings, that part of the bearing to which the bearing alloy is attached, normally by a metallurgical bond.

Backing Bead

See preferred term *backing weld*.

Backing Filler Metal

See *consumable insert*.

Backing Film (Metallography)

A film used as auxiliary support for the thin replica or specimen-supporting film.

Backing Pass (of Weld)

An initial pass of weld to form a surface on which the main weld is deposited. It may remain untouched or be machined away and, possibly, a *back weld deposited*.

Backing Plate

In plastic injection molding equipment, a heavy steel plate that is used as a support for the cavity blocks, guide pins, and bushings. In blow molding equipment, it is a steel plate on which the cavities (i.e., the bottle molds) are mounted. In casting, a second *bottom board* on which molds are open.

Backing Plate/Ring, Strip, etc. (of Weld)

Material placed behind the root of the weld to provide a surface onto which the first weld run is deposited. A temporary backing plate, etc., is one that undergoes little or no fusion and is subsequently removed. A permanent backing plate, etc., is one that is partly fused by the weld and may remain in position or be removed partly after welding. See also *fusible insert*.

Backing Strap

See preferred term *backing strip*.

Backing Strip

Backing in the form of a strip.

Backing Weld

Backing in the form of a weld.

Backing-Split Pipe

See *split pipe backing*.

Backlash

Loss of motion, play, or movement in moving parts such that the driving element (as a gear) can be reversed for some angle or distance before working contact is again made with a driven element.

Backoff

A rapid withdrawal of a grinding wheel or cutting tool from contact with a workpiece.

Back-Pressure Relief Port

An opening in an extrusion die for plastics that allows for the escape of excess material.

Backscatter Techniques/Gauge

The measurement of radiation, usually gamma or beta, reflected from some source by the component under test. Within limits, the amount of reflected radiation increases as a direct function of the thickness of the sample, so the technique is used for applications such as the continuous measurement of sheet during production.

Backscattered Electron

An information signal arising from elastic (electron–nucleus) collisions, wherein the incident electron rebounds from the interaction

with a small energy loss. The backscattered electron yield is strongly dependent upon the atomic number, qualitatively describes the origin of characteristic rays, and reveals compositional and topographic information about the specimen. See also *atomic number imaging*.

Back-to-Back Ring Seal

An adaptation of the simple ring seal that employs two identical elements loaded actually by a spring placed between the rings. The spring forces the elements against mating rings on either side.

Backup (Flash and Upset Welding)

A locator used to transmit all or a portion of the upsetting force to the workpieces or to aid in preventing the workpieces from slipping during the upsetting.

Backup Coat

The ceramic slurry of dip coat that is applied to multiple layers to provide a ceramic shell of the desired thickness and strength for use as a casting mold.

Backward Extrusion

Same as *indirect extrusion*. See *extrusion*.

Baffle

A device used to restrict or divert the passage of fluid through a pipeline or channel.

Bag Molding

A method of molding for bonding plastics or composites involving the application of fluid pressure, usually by means of air, steam, water, or vacuum, to a flexible cover that is sometimes in conjunction with the rigid die and completely encloses the material to be bonded. Also called blanket molding. See also *vacuum bag molding*.

Bagging

Applying an impermeable layer of film over an uncured part and sealing the edges so that a vacuum can be drawn.

Bail

Hoop or arched connection between the core hook and ladle or between the crane hook and mold trunnions.

Bainite

A metastable aggregate of *ferrite* and *cementite* resulting from the transformation of *austenite* at temperatures below the pearlite range but above M_s , the martensite start temperature. Upper bainite is an aggregate that contains parallel lath-shape units of ferrite, produces the so-called “feathery” appearance in optical microscopy, and is formed above approximately 350°C (660°F). Lower bainite, which has an acicular appearance similar to tempered martensite, is formed below approximately 350°C (660°F). Bainite structures normally result from cooling, from the austenitic temperature range, at a rate too rapid to form pearlite but not fast enough to form martensite.

The precise structure is a function of the temperature at which the carbide precipitates. See *steel*.

Bainitic Hardening

Quench-hardening treatment resulting principally in the formation of *bainite*.

Bake

Heating in an oven to a low control temperature to remove gases or to harden a binder. The term is applied to various heating processes involving modest temperatures and no change to the primary properties of the component. For example, components being vitreous enamels require baking to fuse the coating, welding electrodes are baked to drive off moisture from the coating, and components containing high levels of hydrogen, introduced by treatments such as electroplating or welding, are baked to allow the potentially damaging gas to diffuse out.

Baked Core

A casting core that has been heated through sufficient time and temperature to produce the desired physical properties attainable from its oxidizing or thermal-setting binders.

Bakelite

A proprietary name for a phenolic thermosetting resin used as a plastic mounting material for metallographic samples. See *phenol formaldehyde resin*.

Baking

(1) Heating to a low temperature in order to remove gases. (2) Curing or hardening surface coatings such as paints by exposure to heat. (3) Heating to drive off moisture, as in baking of sand cores after molding.

Balance

(1) (Dynamic) condition existing where the principal inertial axis of a body coincides with its rotational axis. (2) (Static) condition existing where the center of gravity of a body lies on its rotational axis.

Balance Construction

In woven reinforcements, it is the equal parts of warp and fill fibers. Construction in which reactions to tension and compression loads result in extension or compression deformations only and in which flexural loads produce fewer bending of equal magnitude and axial and lateral directions.

Balanced Design

In filament-wound reinforced plastics, a winding pattern so designed that the stresses in all filaments are equal.

Balanced Laminate

A laminate in which all laminae at angles other than 0° and 90° occur only in $\pm$ pairs (not necessarily adjacent) and are symmetrical around the centerline. See also *symmetrical laminate*.

B

Balanced Twist

An arrangement of twists in a combination of two or more reinforcing strands that does not kink or twist when the yarn produced is held in the form of an open loop.

Balanced-in-Plane Contour

In a filament-wound part, a head contour in which the filaments are oriented within a plane and the radii of curvature are adjusted to balance the stresses along the filaments with the pressure loading.

Ball (Peen Hammer Ball)

The hammer typically carried by an engineering fitter. It has one smooth hemispherical face and usually a flat square face. The peen end is the likely origin of the term *peening*.

Ball Bearing

A rolling-element bearing in which the rolling elements are spherical. See also *rolling-element bearing*.

Ball Burnishing

(1) Same as *ball sizing*. (2) Removing burrs and polishing small stampings and small machine parts by *tumbling* in the presence of metal balls.

Ball Clay

A secondary clay, commonly characterized by the presence of organic matter, high plasticity, high dry strength, long vitrification range, and a light color when fired. Used extensively in traditional ceramics, such as whiteware, wall tile, and china. See also *traditional ceramics*.

Ball Complement

The number of balls contained in a ball bearing.

Ball Indented Bearing

A bearing with surface indentations serving as a lubricant reservoir.

Ball Mill

A machine consisting of a rotating hollow cylinder partly filled with metal balls (usually hardened steel or white cast iron) or sometimes pebbles; used to pulverize crushed ores or other substances such as pigments or ceramics. The balls may tumble freely in the cylinder or barrel as in the case of mills used for peening or some polarizing processes. Alternatively, in the case of some crushing mills, the balls may run in grooved tracks in a pair of rings. Typically the free-tumbling pulverizing ball would be small, say about 50 mm diameter when charged, while a track ball would be much larger, say about 400 mm.

Ball Milling

A method of grinding and mixing material, with or without liquid, in a rotating cylinder or conical mill partially filled with grinding media such as balls or pebbles.

Ball Sizing

Sizing and finishing a hole by forcing a ball of suitable size, finished, and hardness through the hole or by using a burnishing bar or broach consisting of a series of spherical lands of gradually increasing size coaxially arranged. Depending upon the application, various benefits ensue—burnishing the bore, developing an accurate size, and introducing a favorable pattern of residual stresses. No metal is removed, unlike broaching. Also called *ball burnishing* and sometimes ball broaching.

Balling

(1) Spheroidization. (2) The aggregation of a pasty mass of impure iron and slag in the *puddling process*.

Balling Up

The formation of globules of molten brazing filler metal or flux due to lack of wetting of the base metal.

Banbury

An apparatus for compounding polymeric materials. It is composed of a pair of contrarotating rotors that masticate the materials to form a homogeneous blend. This internal-type mixer produces excellent mixing.

Band Density

In filament winding of composites, the quantity of fiberglass reinforcements per inch of bandwidth, expressed as strands (or filaments) per inch.

Band Mark

An indentation in carbon steel or strip caused by external pressure on the packaging band around cut lengths or coils; it may occur in handling, transit, or storage.

Band Theory

The valence electrons of a metallic crystal are not tied to individual atoms but are shared as a general cloud. The atoms collectively impose a periodic electropotential function that causes the valence electrons to be confined to specific ranges, or bands, of energy level. Individual bands may be partially or completely filled or empty, and they are separated by forbidden bands in which the electrons cannot normally exist other than to jump across. The electrons in partly filled bands can move allowing conduction, hence the terms *conduction electrons* and *conduction band*. See also *atomic structure* and *semiconductor*.

Band Thickness

In filament winding of composites, the thickness of the reinforcement as it is applied to the mandrel.

Banded Structure

A segregated structure consisting of alternating, nearly parallel bands of different compositions, typically aligned in the direction of primary hot working.

Banding

Inhomogeneous distribution of alloying elements or phases aligned in filaments or plates parallel to the direction of working. See also *banded structure*, *ferrite-pearlite banding*, and *segregation banding*.

Bands

(1) Hot-rolled steel strip, usually produced for rerolling into thinner sheet or strip. Also known as hot bands or band steel. (2) See *electron bands*.

Bandwidth

In filament winding of composites, the width of the reinforcement as it is applied to the mandrel.

Bank Sand

Sedimentary deposits, usually containing less than 5% clay, occurring in banks or pits, used in core-making and in synthetic molding sands. See also *sand*.

Bar

(1) A section hot rolled from a *billet* to a form, such as round, hexagonal, octagonal, square, rectangular, with sharp or rounded corners or edges with a cross-sectional area of less than 105 cm³ (16 in.²). (2) A solid section that is long in relationship to its cross-sectional dimensions, having a completely symmetrical cross section and a width or greatest distance between terminal phases of 9.5 mm (3/8 in.) or more. (3) An obsolete unit of pressure equal to 100 kPa. (4) Material produced by rolling or drawing that is usually a simple section but that produced by extrusion may be extremely complex.

Bar Drawing

Tube drawing using a mandrel that travels with the tube.

Bar Folder

A machine in which a folding bar or wing is used to bend a metal sheet whose edge is clamped between the upper folding leaf and the lower stationary jaw into a narrow, sharp, close, and accurate fold along the edge. It is also capable of making rounded folds such as those used in wiring. A universal folder is more versatile in that it is limited to width only by the dimensions of the sheet.

Bar Mill

(1) A rolling mill for producing bar. (2) A barrel or similar container in which components are contained with short lengths of bar and possibly an abrasive. The container is rotated and the bar burnishes or abrades the components.

Bar Stock

Same as *bar*.

Barcol Hardness

A hardness value obtained by measuring the resistance to penetration of a sharp steel point under a spring load. The instrument, called

the Barcol impressor, gives a direct reading on a 0–100 scale. The hardness value is often used as a measure of the degree of cure of a plastic.

Bare Electrode

A filler metal electrode consisting of a single metal or alloy that has been introduced into a wire, strip, or bar form and that has no coating or covering applied to it other than that which was incidental to its manufacturer or preservation.

Bare Glass

Glass in the form of yarns, rovings, and fabrics from which the sizing or finish has been removed. Also, such glass before the application of sizing or finish.

Bare Metal Arc Welding (BMAW)

An arc welding process that produces coalescence of metals by heating them with an electric arc between a bare or lightly coated metal electrode and the work. Neither shielding nor pressure is used as a filler metal is obtained from the electrode.

Barium

A metallic element of the alkaline earth group, symbol Ba. It occurs in combination with the minerals witherite and barite, which are widely distributed. The metal is silvery white and can be obtained by electrolysis from the chloride, but it oxidizes so easily that it is difficult to obtain in the metallic state. Powdered or granular barium is explosive when in contact with carbon tetrachloride, fluorochloromethanes, and other halogenated hydrocarbons. Its melting point is 1562°F (850°C) and its specific gravity 3.78. The most extensive use of barium is in the form of its compounds. The salts, which are soluble, such as sulfide and chloride, are toxic. And insoluble, non-toxic barium sulfate salt is used in radiography. Barium compounds are used as pigments, in chemical manufacturing, and in deoxidizing alloys of tin, copper, lead, and zinc. Barium is introduced into lead-bearing metals by electrolysis to harden the lead. When barium is heated to about 392°F (200°C) in hydrogen gas, it forms barium hydride, BaH₂, a gray powder that decomposes on contact with water and can be used as a source of nascent hydrogen for life rafts. Barium is also a key ingredient in ceramic superconductors.

Barium Chloride

A colorless crystalline material of composition BaCl₂·2H₂O, or in anhydrous form without the water of crystallization. In the mechanical industries, it is used for heat-treating baths for steel, either alone or mixed with potassium chloride. The molten material is free from fuming and can be held at practically any temperature within the range needed for tempering steels. It is also used for making boiler compounds, for softening water, as a mordant in dyeing and printing inks, in tanning leather, in photographic chemicals, and in insecticides. Barium chlorate is a colorless crystalline powder, soluble in water. It is used in explosives as an oxygen carrier and in pyrotechnics for green-colored light. Barium fluoride, BaF₂, is used in crystal form for lasers. Doping with other elements gives diffused wavelengths for different communication beams. Barium cyanide is a poisonous, colorless, crystalline material melting at 1112°F (600°C). A 30% water solution is added to cyanide plating baths that removes carbonates and increases the current efficiency.

B

Barium Nitrate

Also called nitrobarite. A white crystalline powder of composition $\text{Ba}(\text{NO}_3)_2$ with specific gravity of 3.24, melting at 1098°F (592°C), and decomposing at higher temperatures. It is a barium salt of nitric acid obtained by roasting barite with coke, leaching out the precipitated barium sulfide, precipitating as a carbonate by the addition of soda ash, and then dissolving in dilute nitric acid. It has a bitter metallic taste and is poisonous. Barium nitrate is used in ceramic glazes, but its chief use is in pyrotechnics. It gives a pale-green flame in burning and is used for green signals and flares and for white flares in which the delicate green is blended with the light of other extremely luminous materials. It is also used as an oxygen carrier in flare powders and to control the time of burning of the aluminum or magnesium. Sparklers are composed of aluminum powder and steel filings with barium nitrate as the oxygen carrier. The steel filings produced the star-like sparks.

Barium Titanate (BaTiO_3)

The basic raw material used to make high dielectric constant ceramic capacitors. Used also in high thermal conductivity, thick-film ceramic pastes.

Bark

The decarburized layer just beneath the scale that results from heating steel in an oxidizing atmosphere.

Barrel Cleaning

Mechanical or electrolytic cleaning of metal and rotating equipment.

Barrel Distortion

See *negative distortion*.

Barrel Finishing

Improving the surface finish of workpieces by processing them in rotating equipment along with abrasive particles that may be suspended in a liquid. The barrel is normally loaded about 60% full with a mixture of parts, media, compound, and water.

Barrel Plating

Plating articles in a rotating container, usually a perforated cylinder that operates at least partially submerged in a solution.

Barreling

Convexity of the surfaces of cylindrical or conical bodies, often produced unintentionally during upsetting or as a natural consequence during compression testing. See also *compression test*.

Barrier Coat

An exterior coating applied to a composite filament-wound structure to provide protection. In fuel tanks, a coating applied to the inside of the tank to prevent fuel from permeating the sidewall.

Barrier Plastics

A general term applied to a group of lightweight, transparent, impact-resistant plastics, usually rigid copolymers with high acrylonitrile content. Barrier plastics are generally characterized by gas, aroma, and flavor with barrier characteristics approaching those of metal and glass.

Basal Plane

(1) That plane of a hexagonal or tetragonal crystal perpendicular to the axis of highest symmetry. Its Miller indices are (001). (2) A plane perpendicular to the principal axis (*c* axis) in a tetragonal or hexagonal structure.

Basalt

A dense, hard, dark-brown to black igneous rock, consisting of feldspar and augite and often containing crystals of green olivine. It occurs as trapped or as volcanic rock. Basalt is a basalt which is frequently found in columns or prisms, as in the celebrated basalt cliffs of Northern Ireland. It differs from granite in being a fine-grained extrusive rock and in having a high content of iron and magnesium. Basalt is used in the form of crushed stone for paving, as a building stone, and for making rock wool. A Russian cast basalt used for electrical insulators is called angarite. In Germany, cast basalt has been used as a building stone, for linings, and for industrial floors. It is made by melting the crushed and graded basalt and then tempering by slow cooling. The structure of the cast material is dense with needlelike crystals, and it has a Mohs hardness of 8–9. Basalt glass is not basalt, but pumice.

Basalt fiber is alkali resistant; thus it is compatible with concrete and perhaps suitable for infrastructure applications.

Base

(1) A chemical substance that yields hydroxyl ions (OH^-) when dissolved in water. Compare with *acid*. (2) The surface on which a single-point tool rests when held in a tool post. Also known as heel. See also the term *single-point tool*. (3) In forging, see *anvil*.

Base Material

(1) The material to be welded, brazed, soldered, or cut. See also *base metal* and *substrate*. (2) For a printed circuit board, the insulating material upon which a conductor pattern may be formed. The base material may be rigid or flexible, and it may be a dielectric sheet or insulated metal sheet. See also *dielectrics*.

Base Metal

(1) The metal present in the largest proportion in an alloy; brass, for example, is a copper-base alloy. (2) The metal to be brazed, cut, soldered, or welded. (3) After welding, that part of the metal that was not melted. (4) A metal that readily oxidizes, or that dissolves to form ions. Contrast with *noble metal* (2).

Basic Bottom and Lining

The inner bottom and lining of a melting furnace, consisting of materials such as crushed burned dolomite, magnesite, magnesite bricks, or basic slag that gives a basic reaction at the operating temperature.

Basic Dynamic Load Capacity (of a Bearing)

The radial load that a rolling-element bearing can support for a rating life of one million revolutions (500 h at 331/3 rpm). See also *basic load rating*.

Basic Load Rating (C)

The radial load that a ball bearing can withstand for one million revolutions of the inner ring. The value of the basic load rating depends on bearing type, bearing geometry, accuracy of fabrication, and bearing material. See also *basic dynamic load capacity* and *dynamic load*.

Basic Metal

The original metal to which one or more coatings are applied.

Basic NMR Frequency

The frequency, measured in hertz, of the oscillating magnetic field applied to induce transitions between nuclear magnetic energy levels. See also *magnetic resonance*.

Basic Open Hearth Process

The largely obsolete open-hearth process utilizing a basic lining with a lime flux to deal with pig irons and higher phosphorus contents than could be dealt with in the acid open hearth.

Basic Oxygen Furnace

A large tiltable vessel lined with basic refractory material, which is the principal type of furnace for modern steelmaking. After the furnace is charged with molten pig iron (which usually comprises 65%–75% of the charge), scrap steel, and fluxes, a lance is brought down near the surface of the molten metal and a jet of high-velocity oxygen impinges on the metal. The oxygen reacts with carbon and other impurities in the steel to form liquid compounds that dissolve in the slag and gases that escape from the top of the vessel.

Basic Refractories

Refractories whose major constituent is lime, magnesia, or both, and which may react chemically with acid refractories, acid slags, or acid fluxes at high temperatures. Basic refractories are used for furnace linings. Compare with *acid refractory*.

Basic Static Load Rating (of the Bearing)

A load that, if exceeded on a nonrotating rolling-element bearing, produces a total permanent deformation of rolling elements and race at the most heavily stressed contact point of 0.0001 times the ball or roller diameter or greater.

Basic Steel

Steel melted in a furnace with a *basic bottom and lining* and under a slag containing an excess of a basic substance such as magnesia or lime. A steel produced by one of the basic steelmaking processes.

Basket Weave (Composites)

In this type of woven reinforcement, two or more wrap threads go over and under two or more filling threads in a repeat pattern. The basket weave is less stable than the *plain weave* but produces a flatter and stronger fabric. It is also a more pliable fabric than the plain weave and maintains a certain degree of porosity without too much sleaziness, although not as much as the plain weave.

Basket Weave (Titanium)

Alpha platelets with or without interleaved β platelets that occur in colonies in a *Widmanstätten structure*.

Bastard

Usually, anything abnormal, unintended, or otherwise undesirable but sometimes merely a mixture or hybrid. Its use is usually vulgar but not always, for example, a bastard file is a recognized name for a file having a specific cut of medium coarseness.

Batch

A quantity of materials formed during the same process or in one continuous process and having identical characteristics throughout. See also *lot*.

Batch Furnace

A furnace used to heat-treat a single load at a time. Batch-type furnaces are necessary for large parts such as heavy forgings and are preferred for complex alloy grades requiring long cycles. See also *car furnace* and *horizontal batch furnace*.

Batch Sintering

Presintering or sintering in such a manner that compacts are sintered and removed from the furnace before additional unsintered compacts are placed in the furnace.

Bath

Molten metal on the hearth of a furnace, in a crucible, or in a ladle.

Bath Lubrication

See *flood lubrication*.

Batt

Felted fabrics. Structures built by the interlocking action of compressing fibers, without spinning, weaving, or knitting. Used for reinforcing plastic composite materials.

Battery

(1) An accumulator for storing electricity. (2) A factory containing a number of forges. (3) Multiple devices operating in concert.

Bauschinger Effect

The phenomenon by which plastic deformation increases yield strength in the direction of plastic flow and decreases it in another direction.

B

Bauxite

A whitish to reddish mineral composed largely of hydrates of *alumina* having a composition of $\text{Al}_2\text{O}_3 \cdot 2\text{H}_2\text{O}$, theoretically containing 74% alumina. It is the most important ore (source) of aluminum but is also used for making aluminum oxide abrasives, for alumina-based refractories, for white cement, and for decolorizing and filtering.

Bayer Process

A process of extracting alumina from bauxite ore before the electrolytic reduction. The bauxite is digested in a solution of sodium hydroxide, which adversely converts alumina to soluble aluminate. After the “red mud” residue has been filtered out, aluminum hydroxide is precipitated, filtered out and calcined to alumina.

B-Basis

The “B” mechanical property value is the value above which at least 90% of the population of values is expected to fall, with a confidence of 95%. See also *A-basis*, *S-basis*, and *typical basis*.

Beach Marks

Macroscopic progression marks on a fatigue fracture or stress-corrosion cracking surface that indicate successive positions of the advancing crack front. The classic appearances of irregular elliptical or semielliptical rings, radiating outward from one or more origins. Beach marks (also known as clamshell marks or arrest marks) are typically found on service fractures where the part is loaded randomly, intermittently, or with periodic variations in mean stress or alternating stress. Beach marks are visible to the unaided eye and mark the crack front at irregularities in a load cycling such as interruptions in cycling or an abnormal load. Also termed *conchoidal marks*, *shell marks*, or *arrest marks*. Compare with *striations* (metals).

Bead

(1) Half-round cavity in the mold, or half-round projection or molding on a casting. (2) A single deposit of weld metal produced by fusion.

Bead Weld

See preferred term *surfacing weld*.

Beaded Flange

A flange reinforced by a low ridge, used mostly around the hole.

Beading

Raising a ridge or projection on sheet metal.

Beam

(1) A length of material of constant cross section, usually wrought but occasionally cast. (2) A length of material carrying a bending load. (3) A projected stream of radiation.

Beam Hardening

The increase in effective energy of a polyenergetic (e.g., x-ray) beam with increasing attenuation of the beam. Beam hardening is due to the preferential attenuation of the lower-energy, or soft, radiation.

Bearing

A support carrying some component or structure. The term usually implies a small support area and a capacity to allow relative movement of the component being carried, for example, a bearing carrying a rotating shaft.

Bearing Area

(1) The projected bearing or load-carrying area when viewed in the direction of the load. Sometimes used as a synonym for *real area of contact* (this usage is not recommended). (2) The sum of the horizontal intercepts of a surface profile at a given level. (3) The product of the pin (or hole) diameter and the specimen thickness. See also *bearing test*.

Bearing Bronzes

Bronzes used for bearing applications. Two common types of bearing bronzes are copper-base alloys containing 5–20 wt.% tin and a small amount of phosphorus (*phosphor bronzes*) and copper-base alloys containing up to 10 wt.% tin and up to 30 wt.% lead (*leaded bronzes*).

Bearing Characteristic Number

A dimensionless number that is used to evaluate the operating conditions of plain bearings. See also *capacity number* and *Sommerfeld number*.

Bearing Materials

A large variety of metals and nonmetallic materials in monolithic and composite (laminate) form are used for bearings. Monolithic ferrous bearings are made of gray cast iron, pressed and sintered iron and steel powder, and many wrought steels, including low-carbon and high-carbon and plain-carbon steels, low-alloy steels, alloy steels, stainless steels, and tool steels. Most cast-iron bearings are made of gray iron because it combines strength with the lubricity of graphitic carbon. Pressed and sintered bearings can be made to control porosity and impregnated with oil for lubricity. Because of its wide use in ball and roller bearings, one of the best-known bearing steels is American Iron and Steel Institute (AISI) 52100 steel, a through-hardening 1% carbon –1.3% to 1.6% chromium alloy steel. Many steels, however, are simply surface-hardened for bearing applications. In recent years, the performance of bearing steels has been markedly improved by special melting practices that reduce the presence of nonmetallic inclusions.

Monolithic nonferrous bearings include copper (90%)–zinc (10%) bronze, leaded bronzes, and unleaded bronzes and an aluminum–tin alloy, containing about 6% tin as a principal alloying element. The bronze and aluminum alloy provide similar load-bearing capacity and fatigue resistance, but the bronze is somewhat better in resistance to corrosion by fatty acids that can form with petroleum-base oils. It is also less prone to seizure and abrasion from mating shafts, more able to embed foreign matter and, thus, prevent shaft wear, and more tolerant of shaft misalignment.

Applications include auto engine starter-motor bearings, or bushings, for the copper–zinc bronze; auto engine connecting-rod bearings for the aluminum alloy; and various bearings in motors, machine tools, and earth-moving equipment for the tin bronzes.

Monolithic bearings are also made of cemented tungsten and chromium carbides, plastics, carbon graphite, wood, and rubber. Plastics provide good combinations of inherent lubricity, corrosion resistance, and adequate strength at room to moderately elevated temperatures. Thermal conductivity and other performance features that may be required can be provided by metal and other fillers. Plastic bearings can be made of acetal, nylon, polyester, polytetrafluoroethylene, polysulfone, polyphenylene sulfide, polyimide, and polyamide-imide. Carbon–graphite bearings are more heat resistant but rather brittle, thus limited to nonimpact applications. Wood bearings are made of maple and the hard lignum vitae. Rubber bearings, usually steel backed, are used for bearings requiring resilience.

Nonferrous metals are widely used in dual- or trimetal systems. Dual-metal bearings comprise a soft, thin, inner liner metallurgically bonded to stronger backing metal. Steel lined with bronze containing 4%–10% lead provides the highest load-bearing capacity, 55 MPa, or about twice that of the bronze alone, and fatigue strength. However, the aluminum alloy with a steel backing provides the best corrosion resistance and only moderately less load-bearing capacity. Tin and lead babbitt linings excel in surface qualities conducive to free-sliding conditions and are used with either steel, bronze, or aluminum alloy backings.

Dual-metal systems cover a gamut of bearings for motors, pumps, piston pins, camshafts, and connecting rods.

Trimetal bearings, always steel backings, have an inner liner of tin or lead babbitt and an intermediate layer of a more-fatigue-resistant metal, such as leaded bronze, copper–lead, aluminum–tin, tin-free aluminum alloys, silver, or silver–lead. Load-bearing capacity ranges from 10 to 83 MPa. The silver bearing systems provide the best combination of load-bearing capacity, fatigue and corrosion resistance, and compatibility to mating materials, but a lead babbitt, medium-lead bronze, and steel system are a close second, sacrificing only a moderate reduction in corrosion resistance but at a reduction in cost. Applications include connecting rods, camshafts, and main bearings in auto engines and reciprocating aircraft engines.

Bearing Steels

Alloy steels have been used to produce *rolling-element bearings*. Typically, bearings have been manufactured from both high-carbon (1.00%) and low-carbon (0.20%) steels. The high-carbon steels are used in either a through-hardened or a surface induction-hardened condition. Low-carbon-bearing steels are carburized to provide the necessary surface hardness while maintaining desirable core properties.

Bearing Strain

The ratio of the deformation of the bearing hole, in the direction of the applied force, to the pin diameter. Also, the stretch or deformation strain for a sample under bearing load.

Bearing Strength

The maximum bearing stress that can be sustained. Also, the bearing stress at that point on the stress–strain curve at which the tangent is equal to the bearing stress divided by $n\%$ of the bearing hole diameter.

Bearing Stress (Metals)

The shear load on a mechanical joint (such as a pinned or riveted joint) divided by the effective bearing area. The effective bearing area of a riveted joint, for example, is the sum of the diameters of all rivets times the thickness of the loaded member.

Bearing Stress (Plastics)

The applied load in pounds divided by the bearing area. Maximum bearing stress is the maximum load in pounds sustained by the specimen during the test, divided by the original bearing area.

Bearing Test

A method of determining the response to stress (load) of sheet products that are subjected to riveting, bolting, or a similar fastening procedure. The purpose of the test is to determine the *bearing strength* of the material and to measure the *bearing stress* versus the deformation of the hole created by a pin or rod of circular cross section that pierces the sheet perpendicular to the surface.

Bearing Yield Strength

The *bearing stress* at which a material exhibits a specified limiting deviation from the proportionality of *bearing stress* to *bearing strain*.

Bed

(1) The stationary portion of a press structure that usually rests on the floor or foundation, forming the support for the remaining parts of the press and the pressing load. The *bolster* and sometimes the lower die are mounted on the top surface of the bed. (2) For machine tools, the portion of the mainframe that supports the tool, the work, or both. (3) Stationary part of the shear frame that supports the material being sheared and the fixed blade.

Bedding

Sinking a casting pattern down into the sand to the desired position and ramming the sand around it.

Bedding a Core

Placing an irregularly shaped casting core on a bed of sand for drying.

Beer's Law

A relationship in which the optical absorbance of a homogeneous sample containing an absorbing substance is directly proportional to the concentration of the absorbing substance. See also *absorptivity*.

Beilby Layer

A layer of metal disturbed by mechanical working, wear, or mechanical polishing presumed to be without regular crystalline structure (amorphous); originally applied to grain boundaries.

Bell

A jar-like enclosure for containing a vacuum or a controlled atmosphere in sintering equipment.

B

Bell Furnace

A furnace in the shape of an inverted bowl, that is, a bell. The bell is placed over a charge on a fixed hearth and the required heating carried out. The bell can then be transferred to a second and subsequent hearth while the charge on the first hearth cools and is removed. Occasionally, a simple unheated inner bell is left in place to minimize atmospheric contamination and drafts. A top hat furnace is similar.

Bellows

A thin-walled tube with circumferential corrugations that allow repeated longitudinal flexing.

Bellows Seal

A type of mechanical seal that utilizes bellows for providing secondary sealing.

Bell-Type Furnace

A furnace for the sintering of large batches of small pieces under a controlled atmosphere.

Belt Furnace

A continuous-type furnace that uses a mesh-type or cast-link belt to carry parts through the furnace.

Belt Grinding

Grinding with an *abrasive belt*.

Bench Allowance

The length of the arc of the neutral axis between the tangent points of a bend.

Bench Molding

Casting sand molds by hand tamping loose or production patterns at a bench without the assistance of air or hydraulic action.

Bench Press

Any small press that can be mounted on a bench or table.

Bend Angle

The angle through which a bending operation is performed, that is, the supplementary angle to that formed by the two bent tangent lines or planes.

Bend or Twist (Defect)

Distortion similar to warpage generally caused during forging or trimming operations. When the distortion is along the length of the part, it is termed bend; when across the width, it is termed twist. When bend or twist exceeds tolerance, it is considered a defect.

Corrective action consists of hand straightening, machine straightening, or cold restriking.

Bend Radius

(1) The inside radius of a bend section. (2) The radius of a tool around which metal is bent during fabrication.

Bend Tangent

A tangent point at which a bending arc ceases or changes.

Bend Test

A test for determining the relative ductility of metal that is to be formed (usually sheet, strip, plate, or wire) and for determining the soundness and toughness of metal (e.g., after welding). The specimen is usually bent over a specified diameter through a specified angle for a specified number of cycles.

In simpler tests, for example, of general quality or ductility, the test piece is bent in a vice or over an anvil of specified radius. Often the loading is not measured and the test piece is barely bent until it cracks, and to a specified angle or, in a reversed bend, bent to an angle and then bent back. Acceptance criteria depends on the particular test but may range from simply surviving intact to complete freedom from cracking. More complex tests where loading is measured include three-point bend testing in which the test piece is supported at its extremities and the load applied at a single central point. This induces a peak load at the line on the surface opposite the central loading point. For four-point bend testing, the test piece is supported at its extremities and loaded via two points symmetrically located between the support points. This induces an even stress over the length between the two loading points. In tests of fracture toughness, the test piece is precracked and the properties of interest include the stress required to extend the crack, as indicated by potential drop techniques, and the activity at the crack tip as reflected by crack opening displacement.

There are four general types of bend tests, named according to the manner in which the forces are applied to the specimen to make the bend: *free bend*, *guided bend*, *semiguided bend*, and *wraparound bend*.

Bender

Term denoting a die impression, tool, or mechanical device designed to bend forging stock to conform to the general configuration of die impressions to be subsequently used.

Bending

The straining of material, usually flat sheet or strip metal, by moving it around a straight axis lying in the neutral plane. Metal flow takes place within the plastic range of the metal, so that the part retains a *permanent set* after removal of the applied stress. The cross section of the bend inward from the neutral plane is in compression; the rest of the bend is in tension. See also *bending stress*.

Bending Brake

A form of open-frame single-action press that is comparatively wide between the housings, with a bed designed for holding long, narrow forming edges or dies. Used for bending and forming strip, plate, flake, and sheet (into boxes, panels, roof decks, and so on). Also known as *press brake*.

Bending Dies

Dies used in presses for bending sheet-metal or wire parts into various shapes. The work is done by the punch pushing the stock into cavities or depressions of similar shape in the die or by ancillary attachments operated by the descending punch.

Bending Moment

The algebraic sum of the couples or the moments of the external forces, or both, to the left or right of any section on a member subjected to bending by couples or transverse forces, or both.

Bending Rolls

Various types of machinery equipped with two or more rolls to form curve sheet and sections. They have their axes parallel but the center one is offset from the line joining the other two. Bar or sheet passing through the appropriately adjusted rolls is bent to a curve or cylinder.

Bending Stress

A stress involving tensile and compressive forces, which are not uniformly distributed. Its maximum value depends on the amount of flexure that a given application can accommodate. Resistance to bending can be turned to stiffness.

Bending Stress (Glass)

A stress system that simultaneously imposes a compressive component at one surface, graduating to an imposed tensile component at the opposite surface of a glass section.

Bending–Twisting Coupling

A property of certain classes of laminates that exhibit twisting curvatures when subjected to bending moments.

Beneficiation

Concentration or other preparation of ore for smelting.

Bentonite

A colloidal claylike substance derived from the decomposition of volcanic ash composed chiefly of the minerals of the montmorillonite family that are mainly hydrated calcium and magnesium silicates, capable of absorbing five times its weight of water. It is used for bonding molding sand.

Benzene

A colorless, liquid, inflammable, aromatic hydrocarbon that boils at 80.1°C and freezes at 5.4°C–5.5°C. Benzene is used as a solvent and particularly in Europe as a constituent of motor fuel. In the United States, the largest uses of benzene are for the manufacture of styrene and phenol. Other important outlets are in the production of chlorinated benzenes (used in DDT and moth flakes), and benzene hexachloride, and insecticides.

DDT (dichlorodiphenyltrichloroethane) is a colorless, crystalline, tasteless and almost odorless organo-chloride known for its insecticidal properties.

Benzene Ring

The six-carbon ring structure found in benzene, C_6H_6 , and in organic compounds formed from benzene by replacement of one or more hydrogen atoms by other chemical atoms or radicals. The terms aromatic chemicals and aromatics refer to all the chemicals made from the benzene ring.

Nitrobenzene, $C_6H_5NO_2$, is a highly poisonous and inflammable liquid made by the action of nitric and sulfuric acids on benzene, used in soaps and cosmetics. It is called myrbane oil as a perfuming agent. The nitrated derivative called benzedrine, or amphetamine, originally used by wartime pilots to combat fatigue, is phenylaminobenzene. It is used in medicine to control obesity, but it is a stimulant to the central nervous system and is habituating. The isomer dextro-amphetamine is *d*-phenylamino-propane sulfate, commonly called Dexedrine. It causes a rise in blood pressure and stimulates cerebral activity that lasts several hours, but it has a depressant effect on the intestinal muscles, causing loss of appetite and delayed activity of the stomach with other side effects.

Beryl

At least 50 different beryllium-bearing minerals are known, but in only about 30 is it a regular constituent. The only beryllium-bearing mineral of industrial importance is beryl, a hexagonal beryllium-aluminum silicate with the ideal composition $Be_3Al_2Si_6O_{18}$, equivalent to 5% beryllium to 14% beryllium oxide, 19% Al_2O_3 , and 67% SiO_2 . The precious forms of beryl, emerald and aquamarine, approach the ideal composition. Emerald is a transparent, intensely green variety of beryl.

Beryllia

A colorless to white powder of the composition BeO used in the manufacture of hot-pressed ceramic parts—most notably basic refractories and substrates (heat sinks) in electronics. Also known as beryllium oxide.

Beryllium oxide is used in the manufacture of high-temperature refractory material and high-quality electrical porcelains, such as aircraft spark plugs and ultrahigh-frequency radar insulators. The high thermal conductivity of beryllium oxide and its good high-frequency electrical insulating properties find application in electrical and electronic fields.

Another use of beryllium oxide is as a slurry for coating graphite crucibles to insulate the graphite and to avoid contamination of melted alloys with carbon. Beryllium oxide crucibles are used where exceptionally high-purity or reactive metals are being melted. In the field of beryllium oxide ceramics, a type of beryllia has been developed that can be formed into custom shapes for electronic and microelectronic circuits. Beryllium oxide has a high thermal conductivity, equal to that of aluminum, and excellent insulating properties, which permits closer packing of semiconductor functions in silicon integrated circuits.

Berylliosis

A severe illness related to pneumonia resulting from the inhalation of beryllium.

Beryllium

Among structural metals, beryllium (Be) has a unique combination of properties. It has low density (two-thirds that of aluminum), high

B

modulus per weight (five times that of ultrastrength steels), high specific heat, high strength per density, excellent dimensional stability, and transparency to x-rays. Beryllium is expensive, however, and its impact strength is low compared to values for most other metals.

Beryllium is a steel-gray lightweight metal, used mainly for its excellent physical properties rather than its mechanical properties. Except for magnesium, it is the lightest in weight of common metals, with a density of 1855 kg/m³. It also has the highest specific heat (1833 J/kg K) and a melting point of 1290°C. It is nonmagnetic and has about 40% the electrical conductivity of copper, a thermal conductivity of 190 W/m K, high permeability to x-rays, and the lowest neutron cross section of any metal having a melting point above 500°C. Also its tensile modulus (28.9×10^4 MPa) is far greater than that of almost all metals.

Its ultimate tensile strength range is from 228 to 690 MPa and tensile elongation from 1% to 40%, depending on bill form. Thus, because of its low density, beryllium excels in specific strength and especially in specific stiffness. However, tensile properties, especially elongation, are extremely dependent on grain size and orientation and are highly anisotropic so that results based on uniaxial tensile tests have little significance in terms of useful ductility in fabrication or fracture toughness in structural applications. From this standpoint, the metal was considered to be quite brittle. Ductility, as measured by elongation and tensile tests, increases with increasing temperature to about 400°C and then decreases above about 500°C. Although resistant to atmospheric corrosion under normal conditions, beryllium is attacked by O₂ and N₂ at elevated temperatures and certain assets, depending on concentration, at room temperature.

Available forms include block, rod, sheet, plate, foil, extrusions, and wire. Machining blanks, which are machined from large vacuum hot pressings, make up the majority of beryllium purchases. However, shapes can also be produced directly from powder by processes such as cold press/sinter/coin, CIP/HIP, CIP/sinter, CIP/hot press, and plasma spray/sinter. (CIP is cold isostatic press, and HIP is hot isostatic press.) Mechanical properties depend on powder characteristics, chemistry, consolidation process, and thermal treatment. Wrought forms, produced by hot working, have high strength in the working direction, but properties are usually anisotropic.

Beryllium parts can be hot-formed from cross-rolled sheet and plate as well as plate-machined from hot-pressed block. Forming rates are slower than for titanium, for example, but tooling and forming costs for production items are comparable.

Structural assemblies of beryllium components can be joined by most techniques such as mechanical fasteners, rivets, adhesive bonding, brazing, and diffusion bonding. Fusion-welding processes are generally avoided because they cause excessive grain growth and reduce mechanical properties.

Beryllium behaves like other light metals when exposed to air by forming a tenacious protective oxide film that provides corrosion protection. However, the bare metal corrodes readily when exposed for prolonged periods to tap water or seawater or to a corrosive environment that includes high humidity. The corrosion resistance of beryllium in both aqueous and gaseous environments can be improved by applying chemical conversion, metallic, or nonmetallic coatings. Beryllium can be electroless nickel-plated and flame or plasma sprayed.

All conventional machining operations are possible with beryllium, including EDM (Electric Discharge Machining) and ECM (Electric Chemical Machining). However, beryllium powder is toxic if inhaled. Because airborne beryllium particles and beryllium salts

present a health hazard, the metal must be machined in specially equipped facilities for safety.

Machining damages the surface of beryllium parts. Strength is reduced by the formation of microcracks and "twinning." The depth of the damage can be limited during finish machining by taking several light machining cuts and sharpening cutting tools frequently or by using nonconventional metal-removal processes. For highly stressed structural parts, 0.05–0.10 mm should be removed from each surface by chemical etching or milling after machining. This process removes cracks and other surface damage caused by machining, thereby preventing premature failure. Precision parts should be machined with a sequence of light cuts and intermediate thermal stress reliefs to provide the greatest dimensional stability.

Beryllium is toxic if inhaled or ingested, necessitating special precaution in handling. Most applications are quite specialized and stem largely from the good thermal and electrical properties of the metal. Uses include precision mirrors and instruments, radiation detectors, x-ray windows, neutron sources, nuclear reactor reflectors, aircraft brakes, and rocket nozzles.

Beryllium typically appears in military aircraft and space shuttle brake systems and missile reentry body structures, missile guidance systems, and satellite structures. The modulus-to-density ratio is higher than that of unidirectionally reinforced, *high-modulus* boron, carbon, and graphite fiber composites. Beryllium has an additional advantage because its modulus of elasticity is isotropic.

The largest-volume uses of beryllium metal are in the manufacture of beryllium–copper alloys and in the development of beryllium-containing moderator and reflector materials for nuclear reactors. Addition of 2% beryllium to copper forms a nonmagnetic alloy that is six times stronger than copper. These beryllium–copper alloys find numerous applications in industry as nonsparking tools, as critical moving parts in aircraft engines, and in the key components of precision instruments, mechanical computers, electrical relays, and camera shutters. Beryllium–copper hammers, wrenches, and other tools are employed in petroleum refineries and other plants in which a spark from steel against steel might lead to an explosion or fire.

One of the largest uses of beryllium metal is in nuclear reactors as a moderator to lessen the speed of fission neutrons and as a reflector to reduce leakage of neutrons from the reactor core. Beryllium is useful in nuclear applications because of its relatively high neutron-scattering cross section, low neutron-absorption cross section, and low atomic weight.

Another large-scale use of beryllium is in the manufacture of beryllium bronze, which has high tensile strength and a capacity for being hardened by heat treatment. Beryllium–copper molds are used in manufacturing plastic furniture with the appearance of wood-grain surfaces.

A small but important use of beryllium is in foil form as window material in x-ray tubes. Beryllium transmits x-rays 17 times better than any equivalent thickness of aluminum and 6–10 times better than Lindemann glass. This, together with its high melting point, makes possible the use of x-ray beams of greater intensity.

The lightweight, very high elastic modulus, and heat stability of beryllium make it an attractive construction material for use in aircraft and missiles. However, its lack of ductility is a drawback. Were it not for its toxicity and scarcity, beryllium would find use as a rocket fuel because it produces more heat energy per unit volume than any other element. In multistage missiles, a small weight reduction in the final stage, such as might be achieved by using beryllium in place of steel, permits a much larger weight reduction in the earlier stages in terms of fuel and structure. Research in the utilization of beryllium metal and beryllium-containing materials for aircraft and missiles

has been carried out very actively. These and other still developing applications together with the continuing uses of beryllium in nuclear technologies sustain the ever-mounting production levels of beryllium.

The metal is also very expensive. It is also used as an alloying element to produce beryllium–aluminum, beryllium–copper, and beryllium–nickel alloys.

Beryllium Alloys

Dilute alloys of base metals that contain a few percent of beryllium in a precipitation-hardening system are the principal useful beryllium alloys manufactured today. Although beryllium has some solid solubility in copper, silver, gold, nickel, cobalt, platinum, palladium, and iron and form precipitation-hardening alloys with these metals, the copper–beryllium system and, to a considerably lesser degree, the nickel–beryllium alloys are the only ones used commercially.

Other than the precipitation-hardening systems, small amounts of beryllium are used in alloys of the dispersion type wherein there is little solid solubility (aluminum and magnesium). Various amounts of beryllium combine with most elements to form intermetallic compounds. Development of beryllium-rich alloys has been chiefly confined to the ductile matrix beryllium–aluminum, beryllium–copper solid solution alloy with up to 4% copper, and dispersed-phase-type alloys having relatively small amounts of compounds (0.25%–6%), chiefly as beryllium oxide or intermetallics, for dimensional stability, elevated temperature strength, and elastic limit control.

Beryllium–Copper Alloys

Commercial alloys of the beryllium–copper group are divided into cast or wrought types usually and ternary combination such as copper–beryllium–cobalt. Alloys with higher beryllium content have high strength while those with low beryllium have high electrical and thermal conductivity.

Age-hardenable copper–beryllium–cobalt alloys offer a wide range of properties because they are extremely ductile and workable in the annealed condition and are strong and hard after precipitation or aging treatment. Cobalt is added to inhibit grain growth and provide uniform heat treatment response. These alloys also have inherent characteristics of substantial electrical and thermal conductivity and resistance to corrosion and wear, being protected by beryllium oxide films that impart this property to all materials containing beryllium. These age-hardenable alloys resist dimensional change and fatigue.

Primary applications are found in the electronics, automotive, appliance, instrument, and temperature-control industries for electric-current-carrying springs, diaphragms, electrical switch blades, contacts, connectors, terminals, fuse clips, and bellows (foil, strip, and wire), as well as resistance-welding dies, electrodes, clutch rings, brake drums, and switch gear (rod, plate, and forgings). With 1.5% beryllium or more, the melting point of copper is severely depressed and a high degree of fluidity is encountered, allowing casting of intricate shapes with very fine detail. The characteristic is important for plastic injection molds.

For special applications, specific alloys have been developed. Free machining and nonmagnetic alloys have been made, as well as high-purity materials. A precipitation-hardening beryllium–Monel for oceanographic application, containing about 30% nickel, 0.5% beryllium, 0.5% silicon, and the remainder copper, illustrates one of

a series of alloys having strength, corrosion resistance to seawater, and antifouling characteristics.

New applications for structural, aerospace, and nuclear fields are submarine repeater cable housings for transoceanic cable systems, wind tunnel throats, liners for magnetohydrodynamic generators for gas ionization, and scavenger tanks for propane–Freon bubble chambers in high-energy physics research. Important developing applications for beryllium–copper are trunnions and pivot bearing sleeves for the landing gear of heavy, cargo-carrying aircraft, because these alloys allow the highest stress of any sleeve bearing material.

Beryllium–copper master alloys are produced by direct reduction of beryllium oxide with carbon in the presence of copper in an arc furnace. Because Be_2C forms readily, the master alloy is usually limited to about 4.0%–4.25% beryllium. The master alloy is remelted with additional copper and other elements to form commercial alloys. Rolling billets up to 680 kg have been made by continuous-casting techniques.

Beryllium–copper alloys can be fabricated by all the industrial metalworking techniques to produce principally strip, foil, bar, wire, and forgings. They can be readily machined and can be joined by brazing, soldering, and welding. Annealing, to provide high plasticity at room temperature, is accomplished by heat treating (from 790°C to 802°C for the high-beryllium alloys or 900°C–930°C for the low-beryllium alloys) and water quenching. Precipitation hardening is accomplished by heating to 400°C–480°C (low beryllium) and 290°C–340°C (high beryllium).

Alloys with Nickel and Iron

Nickel containing 2% beryllium can be heat-treated to develop their tensile strength of 1700 MPa with 3%–4% elongation. Little commercial use is made of the hard nickel alloys although they have been employed, principally as precision castings, for aircraft fuel pumps, surgical instruments, and matrices and diamond drill bits. Another nickel alloy with 2.0%–2.3% beryllium, 0.5%–0.75% carbon, and the balance of nickel and refractory metals has been used for mold components and forming tools for glass pressware of optical and container quality. Thermal conductivity, wear resistance, and strength, coupled with unusual machinability for a nickel–beryllium alloy, make this alloy particularly advantageous for glassware tooling.

Wrought beryllium–nickel contains about 2% beryllium, 0.5% titanium, and the balance nickel. Casting alloys contain a bit more beryllium (2%–3%) and, in one alloy, 0.4% carbon. Arsenic additions in the case of beryllium–copper alloys has mechanical properties that vary widely, depending on temper condition—from 310 to 1586 MPa in tensile yield strength and Rb 72 to Rc 55 in hardness at room temperature. The alloys retain considerable yield strength at high temperature: 896–1172 MPa at 538°C. They also have good corrosion resistance in general atmospheres and reducing media. Because beryllium is toxic, special precautions are required in many fabricating operations. The wrought alloy is used for springs, bellows, electrical contacts, and feather valves and the casting alloys for molding plastics and glass, pump parts, seal plates, and metal-forming tools.

Attempts have been made to add beryllium to a number of ferrous alloys. Small amounts are used to refine grains and deoxidize ferritic steels in Japan, and promising properties have been developed for austenitic and martensitic steels. Stainless steels (iron–nickel–chromium) may be made maraging by adding 0.15%–0.9% beryllium, developing strengths as high as 1800 MPa as cast or 2300 MPa as rolled while retaining their oxidation- and

B

corrosion-resistant characteristics. Amounts of 0.04%–1.5% beryllium have been added to various iron alloys containing nickel, chromium, cobalt, molybdenum, and tungsten for special applications such as watch springs.

Beryllium-Base Alloys

Three types of beryllium-base alloys are of interest. These consist of dispersed-phase types containing up to 4% beryllium oxide; ductile-phase or duplex alloys of beryllium and aluminum, particularly 38% aluminum in beryllium; and solid solution alloys of up to 4% copper in beryllium.

Dispersed-phase alloys containing oxides, carbides, nitrides, borides, and intermetallic compounds in a beryllium matrix are chiefly characterized by increased strength and resistance to creep at elevated temperatures. Major commercial alloys in the series are of the fine-grain, high-beryllium-oxide (4.25%–6%), hot-pressed types such as materials used for inertial guidance instruments characterized by high dimensional stability, high-precision elastic limit (55–103 MPa), and good machinability.

The 62% beryllium–38% aluminum alloy previously discussed under aluminum alloys was developed as a structural aerospace alloy to combine high modulus and low density with the machining characteristics of the more common magnesium-base alloys. This alloy in sheet form has at room temperature about 344 MPa ultimate strength, 324 MPa yield strength, and about 8% elongation. It is also produced as extrusions. It has a duplex-type microstructure characterized by a semicontinuous aluminum phase. Other alloys of the beryllium–aluminum type have been reported, but the 62% beryllium–38% aluminum alloy is the most used.

Intermetallic Compounds

Beryllium, combined with most other elements, forms intermetallic compounds with high strength at high temperature (up to 552 MPa modulus of rupture at 1260°C), good thermal conductivity, high specific heat, and good oxidation resistance. The beryllium oxide film formed by surface oxidation is protective to volatile oxides (molybdenum) and two elements of high reactivity (zirconium and titanium) at temperatures 1100°C–1500°C and for short times up to 1650°C.

The beryllides are of interest to the nuclear field, to power generation, and to aerospace applications. Evaluation of the intermetallics as refractory coatings, reactor hardware, fuel elements, turbine buckets, and high-temperature bearings has been carried out.

Beryllium Aluminum

The 62% beryllium–38% aluminum alloy developed by Lockheed Aircraft in the 1960s and called Lockalloy. Noted primarily for its light weight and high tensile modulus, thus high specific rigidity, it was used in the form of extrusions for missile skin stiffeners and inrolled sheet on the YF-12 reconnaissance aircraft. The alloy has since become available as a powder-metallurgy product from Brush Wellman Inc. as AlBeMet AM 162 rolled sheet and extruded bar and AlBeMet AM 162H hot isostatic press billet, which contains by weight 60%–64% beryllium, 36%–40% aluminum, and as much as 1 oxygen, 0.1% carbon, and 0.2% each of other metallics. Typical minimum tensile properties of rolled sheet are 379, 276 MPa yield strength, and 5% elongation. The density etc. to 2.123 kg/m³. For the hot isostatically pressed billet, typical minimums are 262, 193 MPa, and 2%, respectively.

Beralcast alloys from Starmet, formerly Nuclear Metals, include beryllium–aluminum 363, 191, 310, and MGA alloys. Having a density of 2160 kg/m³ and a tensile modulus of 202 GPa, 363, 191, and 310 alloys have three to four times the specific rigidity of a 356 aluminum alloy, AZ 91 magnesium, and cast Ti–6Al–4V titanium alloy. They also have one order of magnitude better vibration-damping capacity than 6061 aluminum alloy. Alloys 363 and 191 are for investment casting and contain 61.1%–68.6% beryllium. The 363 also has 2.65%–3.35% silver, 0.65%–1.35% cobalt, and 0.55%–0.95% germanium, with balance aluminum. The 191 has 27.5%–34.5% aluminum, 1.65%–2.5% silicon, and 1.65%–2.35% silver. Ultimate tensile strength is 290 and 197 MPa, tensile yield strength is 214 and 140 MPa, and elongation in 1 in. (2.54 cm) is 3% and 1.7%, respectively.

Beryllium Bronze/Copper

Alloys of copper with up to 3% beryllium. They can be precipitation hardened to a high strength. See preferred term *beryllium–copper*.

Beryllium Oxide

A colorless to white crystalline powder of the composition beryllium oxide, also called beryllia. It has a specific gravity of 3.025, a high melting point, about 2585°C, and a Knoop hardness of 2000. It is used for polishing hard metals and for making hot-pressed ceramic parts. Its high heat resistance and thermal conductivity make it useful for crucibles, and its high dielectric strength makes it suitable for high-frequency insulators. Single-crystal beryllia fibers, or whiskers, have a tensile strength above 6800 MPa.

Ceramic parts with beryllia as the major constituent are noted for their high thermal conductivity, which is about three times that of steel and second only to that of the high-conductivity metals (silver, gold, and copper). They also have high strengths and good dielectric properties. Properties of typical grades of beryllia ceramics are tensile strength, 96 MPa; compressive strength, 2068 MPa; hardness (micro), 1300 Knoop; maximum service temperature, 2400°C; dielectric strength, 5.8. Beryllia ceramics are costly and difficult to work with. Above 1650°C, they react with water to form a volatile hydroxide. Also, because beryllia dust and particles are toxic, special handling precautions are required. Beryllia parts are used in electronic, aircraft, and missile equipment. A more recent application has been the use of beryllia as thermocouple insulators and vacuum furnace equipment operating below 1650°C.

Beryllium oxide powder is available in three particle size ranges: (1) submicron 1–2 mm, used for fabricating both ceramic components and BeO–UO₂ nuclear fuel elements; (2) 2–8 mm, used primarily for fabricating beryllia bodies of 96%–99.5% purity; and (3) ultrahigh density grains of specific size distribution for admixing with resins and other organics to provide very high thermal conductivity coatings and potting compounds.

Beryllia ceramics have these characteristics: outstanding resistance to wetting and corrosion by many metals and nonmetals; mechanical properties only slightly less than those of 96% Al₂O₃ ceramics; valuable nuclear properties, including an exceptionally low, thermal neutron absorption cross section; and ready availability and a wide variety of shapes and sizes. Like Al₂O₃ and some other ceramics, beryllia is readily metallized by a variety of thick- and thin-film techniques.

Major markets for beryllium oxide ceramics are microwave tube parts such as cathode supports, envelopes, spacers, helix supports, collector isolators, heat sinks, and windows; substrates, mounting

pads, and packages for solid-state electronic devices; and bores or plasma envelopes for gas lasers.

Other uses include klystron and ceramic electron tube parts, radiation and antenna windows, and radar antennae. The exceptional resistance of beryllia to wetting (and thus corrosion) by many molten metals and slags makes it suitable for crucibles for melting uranium, thorium, and beryllium.

The high general corrosion resistance of beryllia has helped it capture new applications in the chemical and mechanical fields. And other uses in aircraft, rockets, and missiles are predicted.

Beryllium oxide is tapped for nuclear reactor service because of its refractoriness, high thermal conductivity, and ability to moderate (slow down) fast neutrons. The *thermal* neutrons that result are more efficient in causing fusion of uranium-235. Nuclear industry uses for beryllia include reflectors and a matrix material for fuel elements. When mixed with suitable nuclear poisons, beryllium oxide may be a new candidate for shielding and control rod assembly applications.

The market for electrically insulating, heat-conductive encapsulants based on beryllia grain-polymer mixtures is both small and restricted. Although these composites have thermal conductivities 10–20 times higher than those of other filled plastics, the handling restrictions necessitated by the presence of beryllia limit their use.

Beryllia is used in ceramics to produce gastight glazes. Thin films of the oxide are used on silver and other metals to protect the metal from discoloration. Very thin films are not visible, but heavier films give a faint iridescence. Two other beryllium compounds used especially in chemical manufacturing are beryllium chloride, BeCl_2 , a water-soluble white powder melting at 824°F (440°C), and beryllium fluoride, BeF_2 , melting at 1472°F (800°C). Another beryllium compound, useful for high-temperature, wear-resistant ceramics is beryllium carbide, BeC_2 . Berlox, of the National Beryllia Corporation, is a beryllium oxide powder in particle sizes from 80 to 325 mesh for flame-sprayed, heat- and wear-resistant coatings.

Bessemer Process

A process for making steel by blowing air through molten pig iron contained in a refractory lined vessel so as to remove by oxidation most of the carbon, silicon, and manganese. This process is essentially obsolete in the United States.

Beta (β)

The high-temperature allotrope of titanium with a body-centered cubic crystal structure that occurs above the β transus.

Beta Annealing

Producing a beta phase by heating certain titanium alloys in the temperature range of which this phase forms followed by cooling at an appropriate rate to prevent its decomposition.

Beta Brass

Alloys of copper with zinc in the range of 46%–49% that at ambient temperature comprise beta intermetallic compound.

Beta Compounds

See *electron compounds*.

Beta Eutectoid Stabilizer

An alloying element in titanium that dissolves preferentially in the β phase, lowers the α–β to β transformation temperature, and results in β decomposition to α plus a compound. This eutectoid reaction can be sluggish for some alloys.

Beta Fleck

Alpha-lean region in the α–β titanium microstructure significantly larger than the primary α width. This β-rich area has a β transus measurably below that of the matrix. Beta flecks have reduced amounts of primary α that may exhibit a morphology different from the primary α and the surrounding α–β matrix.

Beta (β) Gage

A gage consisting of two facing elements, a β-ray-emitting source and a β-ray detector. Also called beta-ray gage.

Beta Isomorphous Stabilizer

An alloying element in titanium that dissolves preferentially in the β phase, lowers the α–β to β transformation temperature without a eutectoid reaction, and forms a continuous series of solid solutions with β-titanium.

Beta (β) Loss Peak

In dynamic mechanical or dielectric measurement, the second peak in the damping curve below the melt, in order of decreasing temperature or increasing frequency.

Beta Particles

Particles with a mass similar to that of an electron. They may be positively or negatively charged with an energy up to 4 MeV, a velocity approaching that of light but limited penetrating capacity. They are emitted by a radioactive source undergoing beta decay.

Beta Ray

A ray of electrons emitted during the spontaneous disintegration of certain atomic nuclei.

Beta Structure

A Hume-Rothery designation for structurally analogous body-centered cubic phases (similar to beta brass) or electron compounds that have ratios of three valence electrons to two atoms. Not to be confused with a beta phase on a constitution diagram.

Beta Transus

The minimum temperature above which equilibrium α does not exist in titanium alloys. For β eutectoid additions, the beta transus ordinarily is applied to hypoeutectoid compositions or those that lie to the left of the eutectoid composition.

Betts Process

A process for the electrolytic refining of lead in which the electrolyte contains lead fluosilicate and fluosilicic acid.

B

Bevel

See preferred term, *corner angle*, and also *face mill*.

Bevel Angle

The angle formed between the prepared edge of a member and a plane perpendicular to the surface of a member.

Bevel Flanging

Same as *flaring*.

Bevel Groove

See *groove weld*.

BHN

Brinell hardness number.

Bias

A systematic error inherent in a method (such as temperature effects and extraction inefficiencies) or caused by some artifact or idiosyncrasy of the measurement system (such as blanks, contamination, mechanical losses, and calibration errors). Bias may be both positive and negative, and several types can exist concurrently, so that the net bias is all that can be evaluated except under certain conditions.

Bias Fabric

Fabric consisting of warp and fill fibers at an angle to the length of the fabric.

Biaxial

Applying to or acting on two axes, for example, stresses.

Biaxial Load

A loading condition in which a specimen is stressed in two directions and its plane.

Biaxial Stress

A state of stress in which only one of the *principal stresses* is zero, the other two usually being in tension.

Biaxial Winding

In filament winding, a type of winding in which the helical band is laid in sequence, side by side, with crossover of the fibers eliminated.

Bidirectional Laminate

A reinforced plastic laminate with the fibers oriented in two directions in its plane. A cross laminate. See also *unidirectional laminate*.

Bidirectional Seal

A seal that is designed to seal equally well when the pressure is applied from either direction.

Bifilar Eyepiece

A filar eyepiece with motion in two mutually perpendicular directions.

Bifurcated Forked

A bifurcated rivet has a solid head and a forked shank that is inserted through the sheet materials being joined in the prongs of the fork bent apart.

Bifurcation

The separation of a material into two sections.

Big-End Bearing

A bearing at the larger (crankshaft) end of a connecting rod in an engine. Also known as *bottom-end bearing*, *crankpin bearing*, and *large-end bearing*. See also *little-end bearing*.

Billet

(1) A semifinished section that is hot rolled from a metal *ingot*, with a rectangular cross section usually ranging from 105 to 230 cm² (16–36 in.²), the width being less than twice the thickness. Where the cross section exceeds 230 cm² (36 in.²), the term *bloom* is properly but not universally used. Sizes smaller than 105 cm² (16 in.²) are usually termed bars. (2) A solid semifinished round or square product that has been hot worked by forging, rolling, or extrusion. See also *bar*.

Billet Mill

A primary rolling mill used for making steel billets.

Bimetal Bearing

A bearing consisting of two layers. Bimetal bearings are usually made with a layer of bearing alloy on a bronze or steel backing.

Bimetal Casting

A casting made of two different metals, usually produced by *centrifugal casting*.

Bimetallic

Involving two metals.

Binary

Having two components. The term is often used casually in a metallurgical context in reference to binary phase diagrams.

Binary Alloy

An alloy containing only two component elements.

Binary System

The complete series of compositions produced by mixing a pair of components in all proportions.

Binder (Metals and Ceramics)

(1) In founding, a material other than water, added to foundry sand to bind the particles together, sometimes with the use of heat. (2) In powder technology, a cementing medium: either a material added to the powder to increase the green strength of the compact, which is expelled during sintering, or a material (usually of relatively low melting point) added to a powder mixture for the specific purpose of cementing together powder particles that alone would not sinter into a strong body.

Binder (Plastics)

The resin or cementing constituent (of a plastic compound) that holds the other components together. The agent applied to fiber mat or preforms to bond the fibers before laminating or molding. (2) A component of an adhesive composition that is primarily responsible for the adhesive forces that hold two bodies together. See also *extender and filler*.

Binder Metal

A metal used as a binder. An example would be cobalt in cemented carbides.

Binder Phase

The soft metallic phase that cements the carbide particles in cemented carbides. More generally, a phase in a heterogeneous sintered material that gives solid coherence to the other phase(s) present.

Bingham Solid

An idealized form of solid that begins to flow appreciably only when a certain stress, called the yield stress or yield point, has been exceeded. The solid subsequently flows at a rate proportional to the difference between the applied stress and this yield stress. Many greases can be regarded as Bingham solids.

Binodal Curve

In a 2D phase diagram, a continuous line consisting of both of the pair of conjugate boundaries of a two-phase equilibrium that join without inflection at a critical point. See also *miscibility gap*.

Biological Corrosion

Deterioration of metals as a result of the metabolic activity of microorganisms. Also known as biofouling.

Biomaterials

Materials used to repair, restore, or replace damaged or diseased tissue, or those that comprise parts of artificial organs, artificial tissues, or prostheses. The use of biomaterials dates back to antiquity. Hair, cotton, animal sinew, tree bark, and leather have been used as natural suture materials for almost 4000 years. Synthetic biomaterials are composed of metals, ceramics, polymers, and their composites, and they are often called biomedical materials to differentiate them from natural ones. Gold plates for skull repair were in use in 1000 BC and gold-wire sutures as early as 1550. Besides the mechanical properties of strength, elasticity, and durability, biomaterials need to be nontoxic, sterilizable, and biocompatible. Biocompatibility implies that the material will be inert when in contact with the body and not activate the immune system or lead to blood coagulation. Biomaterials are also categorized as bioabsorbable or nonbioabsorbable. Among the former are the peptides (collagen, fibrin, albumin, and gelatin), hemiacetals (starch, hyaluronic acid, chitin), esters (poly- β -hydroxybutyrate and polymalic acid), and phosphates (DNA and RNA). Synthetic polymers that are bioabsorbable are polylactides, polylactones, polycarbonates, poly- α -cyanoacrylates, polyphosphazenes, and polyanhydrides.

No natural suture material has been so prevalent as catgut, derived from the small intestines of animals, usually the outer serosal layer in cattle or the submucosal layer in sheep. For surgical catgut, or gut, the intestinal tracts of animals are slit lengthwise; the resultant ribbons are twisted into bonded strands and then sterilized by electron-beam irradiation. Catgut becomes too stiff to handle when dry, so it is packed in aqueous alcohol. When the material is treated with a chromic salt solution to prolong in vivo strength, it is called chromic catgut. For a more uniform surface, chromic catgut is treated with glycerin to form glycerin catgut. Catgut varies widely in quality and elicits relatively severe tissue reactions. It is absorbed by the body in 90 days.

A more uniform suture material has been prepared by wind-spinning dispersions of purified collagen into strands. Three kinds of synthetic, absorbable polyester sutures are now marketed. The first is a glycolide homopolymer, also known as poly(glycolic acid) (PGA), obtained by ring-opening polymerization of cyclic diester monomers at high vacuum using tin catalysts. The suture is formed by melt extrusion spinning, followed by hot drawing to give a high orientation and crystallinity, and annealed to improve dimensional stability. It is braided into a multifilament and can be dyed or coated. It is absorbed by the body in 90 days.

Polymer matrices are receiving attention for cell transplant devices to regenerate human tissue in wound healing and reconstruction surgery. Foreskin tissue, type I collagen, a protein that strengthens tissue and is available from animals, has been combined with chondroitin sulfate, a carbohydrate polymer, to form largely porous insoluble matrixes with controlled rate of degradation. Concern over adverse biological reactions of the collagen, however, has prompted the development of matrixes based on synthetic polymers, such as biodegradable polyester, which is widely used for absorbable sutures. Also being studied are hybrids of a degradable polymer such as hyaluronic acid, an anionic polysaccharide of the skin, covalently modified by a small peptide ligand to control biological response. For cartilage tissue, polyesters in the family of polylactides, polyglycolides, and their copolymers are of interest. They degrade mainly by hydrolysis to yield natural metabolic intermediates, most of which then convert to carbon dioxide and water. These polymers are sufficiently strong to make plates and screws for setting bone fractures.

B

Biofix screws, from a Bioscience of Finland, are made of either poly(L-lactide) (PLLA) semicrystalline polyesters or PGA thermoplastic resins and are used to reassemble broken bones. The screws, which are strengthened with sutures of the same materials, hold bone fragments in place during healing, then break down, and are absorbed by the body. An injectable paste, from monocalcium phosphate monohydrate, α -tricalcium phosphate, calcium carbonate, and sodium phosphate solution, speeds treating broken bones with less hardware and less-invasive procedures. After injection, the paste hardens within 10 min and, within 12 h, forms the middle phase of bone—a dahllite, or carbonated apatite—that is at least as strong as natural porous bone.

Joint replacement is one of the largest users of biomaterials. The first implants, artificial hips, were made from 316L low-carbon stainless steel, followed by *chromium–cobalt*, and in the 1970s by titanium. Ti-6Al-4V alloy is the most commonly used, but Kobe Steel's Ti-15Zr-4Ta-4Cb-0.2Pd-0.2O-0.05N is also biocompatible, stronger, and about as ductile. Initially, metal femurs with ball-shaped ends were inserted into the acetabulum, the hip socket, as a direct replacement for the natural femur. Now, the acetabulum itself may be made of metal cups coated with a self-lubricating plastic with good wear properties, such as high-molecular-weight (HMW) polyethylene. A bioactive silicate glass coating and an enameling process for applying ultrathin layers of it to cobalt and titanium alloy implants have been developed at Lawrence Berkeley National Laboratory to enable the implants to bond with bone. Europeans commonly used alumina for femoral balls and acetabular cups, and in the United States, Richards Medical is marketing an alumina-capped femur. Astro Met is developing a partially stabilized zirconia for the same application. Osteonics, of Stryker Corp., uses wrought cobalt alloy compositionally modulated multilayer (CMM) for the femoral cap of hip joints. The cap fits over the top of a hip stem made of either the cast or wrought alloy or a titanium alloy. The cap is within an acetabular cup made of ultrahigh-molecular-weight polyethylene that is mounted in a hemispherical titanium shell. The combination serves as the articulating couple of the hip joint. To reduce friction and wear of the cup, nitrogen ions are implanted in the cap surface. A thin coating of pliable titanium inhibits cracking of yttria-doped zirconia hip joints. It also lessens friction and its related wear debris. Lifecore Biomedical is testing graphite–polysulfone composites, and Zimmer is sheathing titanium in polysulfone or polyether ether ketone (PEEK). PEEK-Optima LT, implant version of Victrex's polyaryletherketone (PAEK) that can match bones' stiffness and toughness, is intended for hip, knee, spine, dental, heart valve, and other body parts. Hyaluronic acid is a viscoelastic liquid used to lubricate the traumatized joints in arthritic patients.

Thermoplastic aromatic polyetherurethanes are used for implants because of their resistance to flexural fatigue, self-bonding characteristics, and good tensile strength. Some grades, however, are degraded by enzymes. Potential uses include insulators for pacemaker leads, long-term in dwelling catheters, and pump diaphragms for artificial hearts. A composite of the copolymer and a silane is seen as a potential replacement for silicone breast implants. Being stronger, the composite is expected to have less tendency to rupture. Also, unlike silicone, it would permit x-ray examination.

A zirconium–palladium–ruthenium alloy developed at National Institute of Standards and Technology (NIST), to extend the life of medical and dental implants, holds promise for hip and knee implants. Extremely wear-resistant, it may reduce the amount of wear debris generated by other implant materials, which, even if inert, can degrade surrounding tissue. A dentin-regenerative protection based on OP-1, a protein that appears to stimulate uncommitted cells to lay down dentin, may preclude a root-canal operation.

Developed by Creative BioMolecules, Inc., it may also be useful in bone reconstruction and in treating osteoporosis. Bioglass, of U.S. Biomaterials, consists of silicon, sodium, and natural bone ingredients—calcium and phosphorus. It can be used to replace middle-ear bone and tooth roots.

To anchor artificial bones in place, they are layered with a porous mating that encourages the growth of natural bone tissue and blood vessels. Because these materials interact with the body, they are called bioactive materials. A porous coating of cobalt–chromium or titanium beads on metal femurs is bioactive. Calcium phosphate ceramics and coatings are osteophilic (bone-loving); their porosity provides the templates on which new bone growth can form for natural healing. Calcium phosphate cement, a dental material initially, can now be used for neurosurgical applications, such as rebuilding part of a person's face lost to cancer, NIST reports. The cement, which the body readily accepts, can replace a section of bone and serve as scaffolding around which new bone forms in the same shape. At present, use is limited to motionless and stress-free body areas.

Hard tissue replacement (HTR) polymer from HDR Sciences, a division of U.S. Surgical, is a porous plastic bead made from polyhydroxyethylmethacrylate and polymethylmethacrylate. It has a negative charge that attracts cell formation in bones and is hydrophilic, so it stays where surgeons place it. It is an open-cell lattice material reinforced with tantalum to replace damaged vertebral bodies and facilitate spinal fusion. It can be implanted between two vertebrae, where bone will infiltrate the porous structure and form a bony fusion at the joint. Hydroxyapatite, a ceramic similar to bone and which bonds to bone naturally, is used to coat bioactive implants. It is applied by plasma spraying, although high-velocity oxyfuel deposition also may be suitable and advantageous due to its lower processing temperature and ease of control. In coating titanium, a common implant material, good results were achieved with high velocity oxygen fuel (HVOF) at the Interdisciplinary Research Center in Biomaterials at Queen Mary College, London. Artificial blood is bioactive. One of the earliest and best known is Fluosol, a perfluorocarbon blood substitute made of perfluorodecalin and perfluorotripropylamine.

Pyrolytic carbon, a pure, glassy carbon developed originally to encapsulate fuel for nuclear reactors, is used for making heart valves because it is inert and extremely wear-resistant; it is also compatible with blood. The valves in the Jarvik-7 artificial heart are made from this material. Medtronic produces highly polished titanium for heart valves and for insulin delivery pumps.

Poly(methylmethacrylate) (PMMA) lenses are implants made of polymethylmethacrylate and are commonly used for patients suffering from severe cataracts. Recent improvements include lenses made of silicone rubber or of hydrogel, a viscous, jellylike polymer. These require a much smaller incision in the eye during insertion, because they are *foldable*. Silicone has been widely used for breast implants, a controversial use that has led to lawsuits by women, alleging leaks from the implants have injured their health. Sulfoxide hydrogel may extend the wear of soft contact lenses and reduce the chance of eye infection by enhancing water in the eye without increasing protein buildup. Excess water in the lens makes it softer, thus more comfortable, while providing oxygen to the eye.

Elastomeric polypeptides that will do work in response to changes in the body's chemical potential have been developed at the School of Medicine, University of Alabama. Polypentapeptide is the parent of this class of biomaterials. They are prepared by solution- and solid-phase peptide synthesis. Elastomeric polypeptides can match the compliance of natural biological tissues and can be modified to obtain desirable tissue reactions to the cellular and enzymatic levels. They can be made to contract and relax in response to changes

in chemical potential analogous to the production of motion in living organisms. Some of their possible biomedical applications are synthetic arteries and ligaments, burn cover materials, and targeted drug delivery systems. In many other product areas, the materials can function as sensors, based on the thermomechanical and chemomechanical transduction properties.

Bipolar Electrode

An *electrode* in an *electrolytic cell* that is *not* mechanically connected to the power supply but is so placed in the electrolyte, between the *anode* and *cathode*, that the part nearer the anode becomes cathodic and the part nearer the cathode becomes anodic. Also called intermediate electrode.

Bipolar Field

A longitudinal magnetic field that creates two magnetic poles within a piece of material. Compare with *circular field*.

Birefringence

A double-refraction phenomenon in anisotropic materials in which an unpolarized beam of light is divided into two beams with different directions and relative velocities of propagation. The amount of energy transmitted along an optical path through a crystal that exhibits birefringence becomes a function of crystalline orientation.

Birefringent Crystal

A crystalline substance that is anisotropic with respect to the velocity of light.

Birotational Seal

A seal that is designed for applications in which a shaft rotation is in either direction.

Biscuit (Metals)

(1) An upset blank for drop forging. (2) A small cake of primary metal (such as uranium made from uranium tetrafluoride and magnesium by bomb reduction). Compare with *derby* and *dingot*.

Biscuit (Plastics)

See *cull* and *preform*.

Bismaleimide (BMI)

A type of polyamide that cures by an addition rather than a condensation reaction, thus avoiding problems with volatile formation, and which is produced by a vinyl-type polymerization of a prepolymer terminated with two maleimide groups. Intermediate in temperature capability between epoxy and polyimide.

Bismuth

Bismuth (Bi) is a brittle, crystalline metal with a high metallic luster with a distinctive pinkish tinge. The metal is easily cast but not readily formed by working. Within a narrow range of temperature, around 225°C, it can be extruded. Its crystal structure is rhombohedral.

It is one of the few metals that expand on solidification; expansion is 3.3%. The thermal conductivity of bismuth is lower than that of any metal, with the exception of mercury.

Bismuth is the most diamagnetic of all metals (mass susceptibility of -1.35×10^6). It shows the greatest Hall effect (increase in resistance under the influence of a magnetic field). It also has a low capture cross section for thermal neutrons (0.034 barn).

Bismuth is inert in dry air at room temperature, although it oxidizes slightly in moist air. It rapidly forms an oxide film at temperatures above its melting point, and it burns at red heat, forming the yellow oxide, Bi_2O_3 . The metal combines directly with halogens and with sulfur, selenium, and tellurium; however, it does not combine directly with nitrogen or phosphorus.

Bismuth is not attacked at ordinary temperatures by air-free water, but it is slowly oxidized at red heat by water vapor. Bismuth does not dissolve in nonoxidizing acids but does dissolve in HNO_3 and in hot concentrated H_2SO_4 . The formation of intermetallic compounds involves mainly the strongly electropositive metals.

Bismuth combined with a number of metallic elements forms a group of interesting and useful low-melting alloys. Some of the lowest melting of these are as follows:

	Melting Point (°C)
49.5 bismuth, 10.1 cadmium, 13.1 tin, 27.3 lead	70
49.0 bismuth, 12.0 tin, 18 lead, 20 indium	57
44.7 bismuth, 5.3 cadmium, 8.3 tin, 22.6 lead, 19.1 indium	47

The fusible alloys are used in many ingenious ways, for example, sprinkler-system triggering devices, bending pipes, anchoring tools during machining, and accurate die patterns.

Bismuth metal (0.1%) is also added to cast iron and steel to improve machineability and mechanical properties. An alloy of 50% bismuth and 50% lead is added to aluminum for screw machine stock, to increase machineability.

A permanent magnet (bisanol) with excellent resistance to demagnetization is produced from manganese and bismuth.

The development of refrigerating systems depending on the Peltier effect for cooling uses a bismuth–tellurium or selenium alloy for thermocouples. Bismuth telluride is used extensively for thermoelectric cooling and for low-temperature thermal electric power production.

Bismuth is playing an important role in nuclear research. Its high density gives it excellent shielding properties for gamma rays while its low thermal neutron capture cross section allows the neutrons to pass through. For investigations in which it is desired to irradiate objects, that is, animals, with neutrons that protect them from gamma rays, castings of bismuth are used as neutron windows in nuclear reactors.

Bismuth has been proposed as a solvent-coolant system for nuclear power reactors. The bismuth dissolves sufficient uranium so that, when the solvent and solute are pumped through a moderator (graphite), criticality is reached and fission takes place. The heat generated from the fission reaction raises the temperature of the bismuth. The heated bismuth is then pumped to conventional heat exchangers producing the steam power required for eventual conversion to electricity.

The advantages of such a reactor are that (1) it has potential for producing low-cost power, (2) it has an integrated fuel processing system, and (3) it converts thorium to fissionable uranium.

B

Another important use of bismuth is in the manufacture of pharmaceutical compounds. Various bismuth preparations have been employed in the treatment of skin injuries; alimentary diseases, such as diarrhea and ulcers; and syphilis. The oxide and basic nitrate are perhaps the most widely used compounds of bismuth. The trioxide is used in the manufacture of glass and ceramic products, and the basic nitrate is used in the porcelain painting to fire on gilt decoration.

Bit

A rotating tool with cutting edges at its tip for drilling holes.

Bit (Soldering)

That part of the soldering iron, usually made of copper, which actually transfers heat (and sometimes solder) to the joint.

Bit Soldering

See preferred term *iron soldering*.

Bitter Pattern

A technique for revealing the magnetic domains at an iron or steel surface. The surface is covered with a suspension of fine magnetic powder in a suitable carrier such as white spirit and the component is then magnetized. The magnetic powder then delineates the domain boundaries. The technique is essentially the same as that used for nondestructive crack detection.

Bitumen

Asphalt-like polymer.

Bituminous Coatings

Bitumens have been defined as mixtures of hydrocarbons of natural or pyrogenous origin or combinations of both (frequently accompanied by their nonmetallic derivatives), which can be gaseous, liquid, semisolid, or solid in which are completely soluble in carbon disulfide.

Bitumens used in the manufacture of coatings are of the semi-solid and solid variety and are derived from three sources:

1. Asphalt produced by the distillation of petroleum
2. Naturally occurring asphalts and asphaltites
3. Coal tar produced by the destructive distillation of coal

It is customary to classify bituminous coatings by their application characteristics as well as by their generic composition, although the coatings can be divided into two classes depending on whether or not they require heating prior to application:

1. *Hot-applied coatings*: These are either 100% bitumen or bitumen coatings blended with selected fillers. A common loading for coatings employing fillers is 10%–20% filler. Hot-applied coatings are brought to the desired application viscosity by heating. The majority of buried pipelines are coated with this type of bituminous coating.
2. *Cold-applied coatings*: These employ both solvents and water to attain the desired application viscosity. A wide range of solvents is used and the choice depends mainly

on the drying characteristics desired and the solvent power required to dissolve the particular bitumen being used. Various fillers are also used in cold-applied coatings to obtain specific applications and end-use properties.

Bituminous coatings can be formulated from many combinations of bitumens, solvents, or dispersing agents and fillers. This makes possible a great variety of end products to meet application and service requirements. The coatings that can be produced range from thin-film (3 mils) coatings to protect machined parts in storage up to thick (100 mils), tough coatings to protect buried pipelines.

As with all other coatings, the conditions of the surface to which a bituminous coating is applied are an important, life-determining factor. A good sandblast is preferred, especially if the surface is badly corroded and the exposure is severe. In any case the surface should be free of moisture, grease, dust, salts, loose rust, and poorly adherent scale. A thin, penetrating bituminous primer can be beneficial on rusty surfaces that can only be cleaned by wire brushing and scraping.

End-Use Requirements

The application will dictate which performance properties of a coating should be given greatest consideration.

Service Temperature

Many applications of bituminous coating require a moderate surface temperature range, often no greater than that caused by weather changes. However, other applications, such as coatings for chemical processing vessels, may require much wider service temperature ranges. In any event, it is possible to obtain good performance with bituminous coatings over a range of -73°C to 163°C .

Thermal and Electrical Insulation

Bitumens themselves are relatively poor thermal insulators. However, by using low-density fillers, coatings with good insulation properties can be formulated. These coatings both protect from corrosion and provide thermal insulation. An added advantage of the coatings is that the insulating material (low-density filler) is completely surrounded by bitumen and is permanently protected from moisture. Thus, they are not subject to a loss in efficiency (as our conventional insulating systems) from damage or failure of the protecting vapor barrier.

Bitumens are naturally good electrical insulators. This is an important consideration in systems using cathodic protection as a complementary corrosion-prevention device.

Abrasion Resistance

Many bituminous coatings need to have high abrasion resistance. Automotive undercoatings, for example, need high abrasion resistance because they are continually buffeted by gravel and debris thrown up by the wheels of the vehicle.

Abrasion-resistant coatings are also used to protect interior surfaces of railroad cars or other vessels handling chemical solids or abrasive slurries.

Weathering Resistance

Asphalt-base bituminous coatings generally weather better than coal-tar-based coatings. Also, there is quite a wide difference in the performance of asphalt coatings derived from different petroleum crudes. By critically selecting the crude and the processing method, asphalt coatings can be formulated that will weather for many years.

In industrial areas, corrosive solids, solutions, and vapors will affect weathering performance. In general, the resistance of bituminous coatings to corrosive media is equal to that of the best organic coatings. Bituminous coatings have good resistance to dilute hydrochloric, sulfuric, and phosphoric acids as well as to sodium hydroxide. They also have good resistance to solutions of ammonium nitrate and ammonium sulfate. However, they have poor resistance to dilute nitric acid, and most coatings are not resistant to oils, greases, and petroleum solvents.

Mechanical Impact and Thermal Shock

Bituminous coatings generally have good adhesion when subjected to mechanical impact. However, where severe mechanical impact is expected, the coatings should first be field-tested or tested in the laboratory under simulated surface conditions.

Resistance to thermal shock is an important consideration in coatings used on some types of processing equipment. Laboratory tests in which a coated panel is transferred back and forth between hot and cold chambers can be used to predict field behavior. Bituminous coatings are available that will withstand thermal shock over a temperature range of -51°C to 60°C .

Types of Coatings

Because bitumens are very dark in color, heavy loadings of pigments are required to produce colors other than black. However, if color is an important consideration, certain colored paints, including whites, can be used as topcoats. Granules can also be blown into the coating before it has completely cured to produce a wide range of decorative effects.

Thin-Film Coatings

Coatings less than 6 mils thick are arbitrarily included in this group. For the most part, these are solvent cutback coatings. They are black except in the case of aluminum paints employing bituminous bases. The coatings are inexpensive and can be used to give good protection from corrosion when color is not important.

Asphalt coatings of this type are used extensively to protect machined parts in storage. Because the coatings retain their solubility of low-cost petroleum solvents even after long weathering, kerosene or similar solvents can be used to remove a coating from the protected part just prior to placing it in service. Coal-tar-based coatings are much more difficult to dissolve and cannot be used for this purpose. However, this property makes coal tar useful for protecting crude-oil tank bottoms and in other applications requiring resistance to petroleum fractions.

Industrial Coatings

Heavy-bodied industrial coatings incorporate low-density and fibrous mineral fillers; coatings can be formulated that will not slump or flow on vertical surfaces when applied as thick as 250 mils. However, they are usually used in thicknesses from 6 to 120 mils.

The coatings are used extensively in industrial plants to protect tanks and structural steel from such corrosive environments as acids, alkalis, salt solutions, ammonia, sulfur dioxide, and hydrogen sulfide gases.

Industrial coatings are also used in large volume by the railroad industry. Complete exteriors of tank cars carrying corrosive liquids are often coated and provide good protection of the saddle area where spillage is likely to occur. Coatings on the exteriors and interiors of hopper cars in dry chemical service also provide protection from both corrosive action and abrasive wear.

Railroad car bituminous cements are used to seal sills and joints in boxcars. An application of this material followed by an overcoating of granules makes an excellent roofing system for railroad cars.

Coatings for Use Over Insulation

Practically all industrial insulating materials must be protected from the weather and moisture; otherwise they would lose their efficiency. Bituminous coatings formulated to have low rates of moisture vapor transmission give best results on installations operating at low (-73°C) to moderate (82°C) temperatures. Coatings that allow a higher rate of moisture transmission (breathing type) are needed to protect the insulation on systems operating at 82°C and above. This is necessary so that moisture trapped beneath the coating can escape when the unit is brought to operating temperatures.

Thermal Insulating Coatings

Low-density fillers can be employed in bituminous mastics to produce coatings with relatively good insulating values; a k value of $0.6 \text{ Btu/ft}^2/\text{h}/^{\circ}\text{F}$ is typical. Insulating coatings are usually applied somewhat more quickly than conventional mastics to obtain the insulating value desired. They are commonly used in thicknesses of 252–275 mils, and because of their thickness and resiliency, they have excellent resistance to mechanical damage.

Automotive Underbody Coatings

These are mastic-type coatings containing fibrous and other fillers. They are used to coat the undersides of floor panels, fenders, gasoline tanks, and frames to protect against corrosion and provide sound deadening and joint sealing.

The coatings have high resistance to deicing salts, moisture, and water. They also have *sound-deadening properties that noticeably* reduce the noise level inside an automobile. This provides for a more pleasant and less fatiguing ride. The sealing and bridging action of the coatings is also especially effective in reducing drafts and dust infiltration.

Sound-Deadening Coatings

High-efficiency, sound-deadening coatings can be formulated from selected resinous bases and high-density fillers. They have better sound-deadening properties than automotive underbody coatings and are used on the wall, roof, and door panels of automotive equipment where sound deadening is the primary need, rather than abrasion resistance or protection from corrosion. They are also used on railroad passenger cars, house trailers, stamped bathtubs, kitchen sinks, air-conditioning cabinets, and ventilation ducts.

Pipe Coatings

Industrial coatings are excellent for protection of pipe above-ground. However, the environment of underground exposure and the complementary use of cathodic protection make it necessary to use specially designed coatings. The stresses created by shrinking and expanding soil require that the coating be very tough. Rocks and other sharp objects can be expected to cause high localized pressures on the coating surface. A coating must have good cold flow properties to resist penetration by objects, which can cause localized pressures as high as 690 MPa.

Cathodic protection (and impressed negative electrical potential) is widely used to prevent the corrosion processes from occurring at flaws

B

in the pipe coatings. Both asphalts and coal tars are good electrical insulators and make excellent coatings for cathodic protection applications.

Coatings for pipe are usually of the hot application type. Application can be made at the mill and a special pipe-coating yard, or over the ditch, depending on the terrain, size of pipe, and other factors. The coating may be given added strength by embedding it with a glass fabric while it is still hot. Outer wrappings of rag, asbestos, and glass felts are sometimes used to give added resistance to damage by soil stresses.

Application

Bituminous coatings that are cut back with solvents or emulsified with water can be produced to consistencies suitable for application by dipping, brushing, spraying, or troweling at ambient temperatures.

Dipping is usually used to coat small parts. As a rule coating viscosity is adjusted to produce a thickness of 1–6 mils.

Brushing is used on areas that cannot be reached by spraying and on jobs that do not warrant setting up spraying equipment. Coating thicknesses can range from 1 to 65 mils.

Spraying is the most popular method for applying cold coatings. The thickness required in one application determines the consistency of the formulation, and thicknesses of 1–250 mils are obtainable by spraying. Conventional paint-spray equipment can be used for coatings up to 6 mils thick. Heavier coatings require the use of mastic spray guns fed from pressure pots or heavy-duty pumps. Heated vessels and feed lines can also be used to decrease viscosity and permit faster application and buildup of thicker films in one application.

Troweling is usually used in inaccessible areas or where it is necessary to produce a very heavy coating in one application. Trowel coats are usually applied in thicknesses above 250 mils.

Bituminous coatings can also be applied hot without the need for any diluents. Such coatings are widely used on piping in thicknesses of about 95 mils. They are heated to 177°C–288°C and then pumped into a special apparatus that surrounds and travels along the pipe.

Bivariate Equilibrium

A stable state among several phases equal to the number of components in a system and in which any two of the external variables of temperature, pressure, or concentration may be varied without necessarily changing the number of phases. Sometimes termed divariant equilibrium.

Black Annealing

Box annealing or pot annealing ferrous alloy sheet, strip, or wire to impart a black color to the oxidized surface. See also *box annealing*.

Black Light

Electromagnetic radiation not visible to the human eye. The portion of the spectrum generally used in fluorescent inspection falls in the ultraviolet region between 330 and 400 nm, with the peak at 365 nm.

Black Liquor

The liquid material remaining from pulpwood cooking in the soda or sulfate papermaking process.

Black Marking

Black smudges on the surface of a pultruded plastic product that results from excessive pressures in the die when the pultrusion is

rubbing against it or unchromed die surfaces and that cannot be removed by cleaning or scrubbing or by wiping with solvent.

Black Oxide

A black finish on a metal produced by immersing it in hot oxidizing salts or salt solutions.

Black Spot(Ting)

Casting porosity filled with carbon-rich material. The term is usually used when the defects are exposed by machining.

Blackbody

A hypothetical “body” that completely absorbs all incident radiant energy, independent of wavelength and direction, that is, neither reflects nor transmits any of the incident radiant energy.

Blackbody Radiation

The radiation emitted by a theoretical perfect *blackbody*.

Blackheart Malleable

See *malleable cast iron*.

Blacking

Carbonaceous materials, such as graphite or powdered carbon, usually mixed with a binder and frequently carried in suspension in water or other liquid used as a thin facing applied to surfaces of molds or cores to improve casting finish.

Blacksmith Welding

See preferred term *forge welding*.

Bladder

An elastomeric lining for the containment of hydroproof or hydroburst pressurization medium and filament-wound structures.

Blade-Setting Angle

See preferred term *cone angle*.

Blank

(1) In forming, a piece of sheet metal, produced in cutting dies, that is usually subjected to further press operations. (2) A pressed, presintered, or fully sintered powder metallurgy compact, usually in the unfinished condition and requiring cutting, machining, or some other operations to produce the final shape. (3) A piece of stock from which a forging is made, often called a *slug* or *multiple*. (4) Any article of glass on which subsequent forming or finishing is required. (5) In various test procedures especially chemical analysis, a sample that does not contain the material being investigated or analyzed but which is subject to the full test procedure to identify any experimental error or contamination.

Blank Carburizing

Simulating the carburizing operation without introducing carbon. This is usually accomplished by using an inert material in place of the carburizing agent or by applying a suitable protective coating to the ferrous alloy.

Blank Nitriding

Simulating the nitriding operation without introducing nitrogen. This is usually accomplished by using an inert material in place of the nitriding agent or by applying a suitable protective coating to the ferrous alloy.

Blanket

Fiber or fabric plies that have been laid up in a complete assembly and placed on or in the mold all at one time (flexible bag process). Also, the type of bag in which the edges are sealed against the mold.

Blankholder

(1) The part of a drawing or forming die that holds the workpiece against the drawer ring to control metal flow. (2) The part of a drawing or forming die that restrains the movement of the workpiece to avoid wrinkling or tearing of the metal.

Blanking

The operation of punching, cutting, or shearing a piece out of stock to a predetermined shape.

Blanking Press

A machine for stamping out *blanks*.

Blast Furnace

A vertical shaft smelting furnace for producing pure pig iron from iron ore. The charge, loaded at the top, comprises iron ore, limestone as flux, coke as fuel, and reducing agent. The preheated air blast injected around the periphery at about a quarter height increases the temperature derived from burning the coke to about 1800°C. Carbon monoxide formed by the coke reduces the iron oxide to molten iron. The limestone combines with the contaminants to produce a fluid slag. The slag and impure pig iron are tapped off separately close to the bottom. Similar processes are used for some other metals. For example, where the temperature can be lower, as in smelting of copper, lead, and tin ores, a smaller furnace is economical, and preheating of the blast is not required.

Blasting or Blast Cleaning

A process for cleaning or finishing metal objects with air blast or centrifugal wheel that throws abrasive particles against the surface of the workpiece. Small, irregular particles of metal are used as the abrasive in grit blasting; sand, in sandblasting; and steel, in shot blasting.

Blebs

Blebbing growths of material on the exterior of ingots or castings as a result of inverse segregation. As they tend to contain a

disproportionate amount of alloying and impurity, they may be relatively hard and brittle causing problems in subsequent operations.

Bleed

(1) To give up color when in contact with water or a solvent. Undesirable movement of certain materials in a plastic, such as plasticizers in vinyl, to the surface of the finished article or into an adjacent material; also called migration. (2) Refers to molten metal oozing out of a casting. It is stripped or removed from the mold before complete solidification.

Bleeder Cloth

A woven or nonwoven layer of material used in the manufacture of composite parts to allow the escape of excess gas and resin during cure. The bleeder cloth is removed after the curing process and is not part of the final composite.

Bleeding

(1) The removal of excess resin from a laminate during cure. The diffusion of color from a plastic part into the surrounding surface or part. (2) Separation of oil (or other fluid) from a grease. (3) Exudation of metal, usually high in impurities, from the newly solidified surface of a cooling ingot. See solidification. (4) The trail of red iron oxide seeping from an interface suffering from *fretting*.

Bleedout

The excess liquid resin that migrates to the surface of a winding. Primarily pertinent to filament winding.

Bleed-Out

The spread of adhesive away from the bond area.

Blemish

A nonspecific quality control term designating an imperfection that mars the appearance of a part but does not detract from its ability to perform its intended function.

Blend (Noun)

Thoroughly intermingled powders of the same nominal composition.

Blended Sand

A mixture of sands of different grain size and clay content that provides suitable characteristics for foundry use.

Blending

(1) In powder metallurgy, the thorough intermingling of powders of the same nominal composition (not to be confused with *mixing*). (2) The process of mixing mineral oils to obtain the desired consistency. Blending should be contrasted with compounding, which utilizes additives.

Blind Hole

A hole that is not drilled entirely through.

B

Blind Joint

A joint, no portion of which is visible.

Blind Riser

A *riser* that does not extend through the top of the mold.

Blind Rivet

A rivet that requires access to one side only for insertion and securing. For example, see *pop rivet*.

Blind Sample

A sample submitted for analysis whose composition is known to the submitter but unknown to the analyst, used to test the efficiency of a measurement process.

Blister (Adhesives)

An elevation of the surface of an adherend, the shape of which somewhat resembles a blister on the human skin. Its boundaries may be definitely outlined, and it may have burst and become flattened. A blister may be caused by insufficient adhesive; inadequate curing time, temperature, or pressure; or trapped air, water, or solvent vapor.

Blister (Ceramics)

A defect consisting of a bubble that forms during fusion and remains as porcelain enamel solidifies.

Blister (Metals)

(1) A casting defect, on or near the surface of the metal, resulting from the expansion of gas, almost invariably hydrogen, in a subsurface zone. It is characterized by a smooth bump on the surface of the casting and a hole inside the casting directly below the bump. (2) A raised area, often dome shaped, resulting from loss of adhesion between a coating or deposit and the basis metal.

Blister Copper

An impure intermediate product in the refining of copper, produced by blowing copper *matte* in a converter, the name being derived from the large blisters on the cast surface that result from the liberation of SO₂ and other gases.

Blister Steel

An early form of steel produced by recarburizing a good-quality wrought iron by heating in charcoal.

Blistering

The development during firing of enclosed or broken macroscopic vesicles or bubbles in a body, or in a glaze or other coating.

Block

A preliminary forging operation that roughly distributes metal preparatory for *finish*.

Block and Finish

The forging operation in which a part to be forged is blocked and finished in one heat through the use of tooling having both a block impression and a finish impression in the same die block.

Block Brazing

A brazing process in which the heat required is obtained from heated blocks applied to the parts to be joined.

Block Copolymer

An essentially linear copolymer consisting of a small number of repeated sequences of polymeric segments of different chemical structure.

Block Grease

A grease that is sufficiently hard to retain its shape and block or stick form.

Block Sequence

A combined longitudinal and buildup sequence for a continuous multiple-passed weld in which separated lengths are completely or partially built up in cross section before intervening lengths are deposited. See also *backstep sequence* and *longitudinal sequence*.

Blocked Curing Agent

A curing agent or hardener rendered unreacted, which can be reactivated as desired by physical or chemical means. Compare with *hardener*.

Blocker

The impression in the dies (often one of a series of impressions in a single die set) that imparts to the forging an intermediate shape, preparatory to forging of the final shape. Also called blocking impression.

Blocker Dies

Forging dies having generous contours, large radii, drift angles of 7° or more, and liberal finish allowances. See also *finish allowance*.

Blocker-Type Forging

A forging that approximates the general shape of the final part with relatively generous *finish allowance* and radii. Such forgings are sometimes specified to reduce die costs where only a small number of forgings are described and the cost of machining each part to its final shape is not excessive.

Block, first, second, and finish: The forging operation in which a part to be forged is passed in progressive order through three tools mounted in one forging machine; only one is involved for all three operations.

Blocking

In forging, a preliminary operation performed inclosed eyes, usually hot, to position metal properly so that in the finish operation,

the dies will be filled correctly. Blocking can ensure proper working of the material and can increase die life.

Blocking (Adhesives)

An undesired adhesion between touching layers of a material, such as occurs under moderate pressure during storage or use.

Blocking (Glass)

(1) The process of shaping a gather of glass in a cavity of wood or metal. (2) The process of stirring and fining glass by immersion of a wooden block or other source of bubbles. (3) The process of reprocessing to remove surface imperfections. (4) The mounting of optical glass blanks in a shell for grinding and polishing operations. (5) The process wherein a furnace is idled at reduced temperatures. (6) The process of setting refractory blocks in a furnace.

Blocking Impression

Same as *blocker*.

Blocky Alpha

Alpha phase in titanium alloys that is considerably larger and more polygonal in appearance than the primary α in the sample. It may arise from extended exposure high in the α - β phase field or by slow cooling through the β transus during forging or heat treating. It may be removed by β recrystallization, or all- β working, followed by further α - β work, and may accompany grain boundary α .

Bloom

(1) A semifinished hot-rolled product, a rectangular cross section, produced on a blooming mill. See also *billet*. For steel, the width of a bloom is not more than twice the thickness, and the cross-sectional area is usually not less than 230 cm² (36 in.²). Steel blooms are sometimes made by forging. (2) A visible exudation or efflorescence on the surface of an electroplating bath. (3) A bluish fluorescent cast to a painted surface caused by deposition of a thin film of smoke, dust, or oil. (4) A loose, flowerlike corrosion product that forms when certain metals are exposed to a moist environment. See *algae growth*.

Bloom (Plastics)

A noncontinuous surface coating on plastic products that comes from ingredients such as plasticizers, lubricants, and antistatic agents that are incorporated into the plastic resin or that occurs by atmospheric contamination. Bloom is the result of ingredients in the plastic coming out of solution and migrating to the surface.

Bloomer

The mill or other equipment used in reducing steel ingots to blooms.

Blooming Mill

A primary rolling mill for stage rolling of ingots used to make blooms.

Blotter

In grinding, a disk of compressible material, usually blotting-paper stock, used between the grinding wheel and its flanges to avoid concentrated stresses.

Blow

A term that describes the trapping of gas in castings, causing voids in the metal. Also (as in “*the blow*” and “*after blow*”) the periods in which air or other gas is being injected during the Bessemer and other injections in steelmaking processes.

Blow Hole

(1) An internal void in cast metal, including weld metal, resulting from the entrapment of gas during solidification. Such holes may occur throughout the casting, within the grains, and then the boundaries. The term usually implies voids of substantial size, and in the case of weld metal in particular, voids smaller than about 1.5 mm diameter are usually termed *gas pores*. See also *porosity*. (2) A void in a solder connection caused by outgassing or a void in a fired dielectric.

Blow Holes

In casting technology, holes in the head plate or blow plate of a core blowing machine through which sand is blown from the reservoir into the *core box*.

Blow Molding

Essentially, blow molding involves trapping a hollow tube of thermoplastic material in a mold. Air pressure applied to the inside of the heated tube blows the tube out to take the shape of the mold. There are many variations on the basic technique.

In short, the process is an economical high-speed, high-production-rate method of forming thermoplastic parts of hollow shape, or parts that can be simply made from a hollow shape.

Uses include the container and toy field, where bottles and toys in many different shapes are formed in large quantities at low cost. The most commonly used material is polyethylene (PE).

Although any thermoplastic resin can be considered a candidate for blow molding, PE was the first used when blow molding started with low-density PE for blow-molded squeeze bottles. Now, low-, intermediate-, and high-density PE resins are used, as well as special ethylene copolymers designed to provide greatly improved stress cracking resistance compared with PE homopolymers, needed for detergent containers.

One of the main criteria of selection of a PE resin for blow molding is the proper balance of physical properties required for the specific use.

With the extension of blow molding into broader use in industrial products, the need for engineering properties other than those of PE has stimulated interest in other thermoplastics. The main plastics available for blow molding, other than PE, include cellulose, polyamides (nylons), polyacetals, polycarbonates, polypropylene, and vinyls.

The cellulosic family of plastics includes acetate, butyrate, propionate, and ethyl cellulose. For blow molding, the cellulose offer strength, stiffness, transparency, and high surface gloss. They have unlimited color possibilities. Chemical resistance and availability

B

of nontoxic resins make them potentially suitable for medicine and food packaging. Their strength, stiffness, and transparency make them suitable for industrial parts, toys, and numerous decorative and novelty items.

Polyamides or nylons, although relatively high-cost materials, offer potential benefits in industrial parts in special containers, such as aerosols. Special developments have resulted in formulations tailored to special viscosity requirements for blow molding.

Polyacetal resins for blow molding offer toughness, rigidity, abrasion resistance, high heat distortion temperatures, and excellent resistance to organic solvents. Also, they are resistant to aliphatic and aromatic hydrocarbons, alcohols, ketones, strong detergents, weak organic acids, and some weak inorganic bases. Aerosol containers are another application for blow molding.

Polycarbonates have found their place in blow-molded industrial parts. Primarily they offer high toughness, strength, and heat resistance. They are transparent with almost unlimited colorability and are self-extinguishing.

Polypropylenes, somewhat similar to higher-density PE's but with lower specific gravity; higher rigidity, strength, and heat resistance; and lower permeability, offer interesting properties at a low cost. Because of their lower permeability, they are used in containers where PE is unsuited. They also have excellent stress-crack resistance.

Polyvinyl chloride (PVC) for blow-molded parts offers benefits in terms of variability of engineering properties. PVCs are available with properties ranging all the way from high rigidity in the unplasticized grades to highly flexible plasticized PVCs. The variability in performance resulting from the many possible formulations means that engineers must consult with the material supplier and attempt to obtain a formulation with the proper performance and processing characteristics to meet their needs.

The scope of blow-molded design has already broadened beyond that of round hollow objects. Production of such parts as housings by blowing a unit and sawing the item along the parting line to produce two housings is already a reality. As many as 10 cavities have been incorporated into a mold, using a wide tube and allowing air to pass through a hollow sprue or runner system between parts.

The future design possibilities of blow molding appear bright. The constant improvements in equipment design continue to add flexibility to the blow-molding process.

Secondary Operations

The equipment used will determine to a great extent the amount of finishing required on the parts. Parts must usually be trimmed and often decorated. Trimming may be made by hand, or may involve highly automated trimming, reaming, and cutting.

Decorating of parts depends on the shape of the part and the type of material used. But generally, a variety of techniques is available, including labeling, hot stamping, silk screening, and offset printing.

By far the largest market for blow-molding applications is in the container field, ranging from containers for food, drugs, and cosmetics to household and industrial chemicals. Toys and housewares represent sizable markets.

The industrial product area represents one of the biggest potential uses for the process. Present products include controls for television sets, rollers for lawnmowers, oil dispensers, toilet floats, molds for epoxy potting, and auto ducting for air-conditioning.

Blow Pin

Part of the tooling used to form hollow plastic objects or containers by the blow molding process. It is a tubular tool through which

air pressure is introduced into the parison to create the air pressure necessary to form the parison into the shape of the mold. In some blow molding systems, it is a part of, or an extension of, the core pin.

Blow Pressure

The air pressure required to form the parison into the shape of the mold cavity, in a plastic blow molding operation.

Blow Rate

The rate of speed at which air enters, or the time required for air to enter, the parison during the *blow molding cycle*.

Blowdown

(1) In corrosion prevention, injection of air or water under high pressure through a tube to the anode area for the purpose of purging the annular space and possibly correcting high resistance caused by gas blocking. (2) In connection with boilers or cooling towers, the process of discharging a significant portion of the aqueous solution in order to remove accumulated salts, deposits, and other impurities.

Blowing Agent

A compounding ingredient used to produce gas by chemical or thermal action, or both, in the manufacture of hollow or cellular plastic articles.

Blown Oil

Fatty oil that is artificially thickened by blowing air through it.

Blown Tubing

A thermoplastic film that is produced by extruding a tube, applying a slight internal pressure to the tube to expand it while still molten, and subsequently cooling to set the tube. The tube is then flattened through guides and wound up flat on rolls. The size of blown tubing is determined by the flat width in inches as wound rather than by the diameter, as in the case of rigid types of tubing.

Blown-Film Extrusion

Technique for making film by extruding the plastic through a circular die, followed by expansion (by the pressure of internal air admitted through the center of the mandrel), cooling, and collapsing of the bubble.

Blowpipe (Brazing and Soldering)

A device used to obtain a small, accurately directed flame for fine work, such as in the dental and jewelry trades. Any flame may be used, a portion of it being blown to the desired location for the required time by the blowpipe that is usually mouth operated.

Blowpipe (Welding and Cutting)

See preferred terms *welding torch* and *cutting torch*.

Blow-Up Ratio

In *blow molding* of plastics, the ratio of the diameter of the product (usually its greatest diameter) to the diameter of the parison from which the product is formed. In blown film extrusion, the ratio between the diameter of the final film tube and the diameter of the die orifice.

Blue Anneal

The annealing of steel without any protection from the environment at a temperature of about 750°C–800°C. This avoids the severe oxidation associated with full annealing or normalizing and the resultant adherent dark blue oxide film may be a desirable feature.

Blue Brittleness

Brittleness exhibited by some steels after being heated to some temperature within the range of about 205°C–370°C (400°F–700°F), particularly if the steel is worked at the elevated temperature. Killed steels are virtually free of this kind of brittleness.

Blue Dip

A solution containing a mercury compound, once widely used to deposit mercury on a metal by immersion, usually prior to silver plating.

Blue Enamel

(1) In dry-process porcelain enameling, an area of enamel coating so thin that it appears blue in color. (2) In wet-process enameling, a cover coat applied too thinly to hide the substrate.

Blueing (Plastics)

A mold blemish in the form of a blue oxide film on the polished surface of a mold due to abnormally high mold temperatures.

Bluing (Metals)

Subjecting the scale-free surface of a ferrous alloy to the action of air, steam, or other agents at a suitable temperature, thus forming a thin blue film of oxide and improving the appearance and resistance to corrosion. This term is ordinarily applied to sheet, strip, or finished parts. It is used also to denote the heating of springs after fabrication to improve their properties.

Blushing

(1) Whitening and loss of gloss of a usually organic coating caused by moisture. Also called blooming. (2) The condensation of atmospheric moisture at the adhesive bond line interface.

B₄C Whiskers

These are single crystals of B₄C or B₁₃C₂ that range in diameter from 1 to 10 mm and average length of 30–300 mm. B₄C whiskers have been utilized in matrices of Al₂O₃, SiC, and Si₃N₄. Toughness values exceeding 9.0 MPa m^{1/2} have been reported in a matrix of Al₂O₃.

B₄C whiskers have been tested in metal–matrix composites with high values reported in ductility.

Another boron compound used for the production of high-temperature ceramic parts by pressing and sintering is boron silicide (B₄Si). It is a black, free-flowing crystalline powder. The powder is microcrystalline, with particles about 75 μm in diameter, and the free silicon is less than 0.15%. This compound normally reacts at 1200°C to form B₆Si and silicon, but when compacted and centered, the ceramic forms a boron silicate oxygen protective coating, and the parts have a serviceable life in air at temperatures to 1400°C. Molded parts have high thermal shock resistance and can be water-quenched from 1093°C without shattering.

In combination with plastics or aluminum, boron provides an effective lightweight neutron-shielding material. Boron-containing shields are valuable because of their satisfactory mechanical properties and because boron absorbs neutrons without producing high-energy gamma rays. Rods and strips of boron steel have been used extensively as control rods in atomic reactors.

The physical properties that make boron attractive as a construction material in missile and rocket technology are its low density (15% lighter than aluminum), extreme hardness, high melting point, and remarkable tensile strength in filament form. Production of boron fibers by vapor deposition methods has been developed on a commercial scale. These fibers are being used in an epoxy (or other plastic) carrier material or matrix. The resulting composite is stronger and stiffer than steel at 25% lighter than aluminum. The balance of strength and stiffness of the composite makes it ideal for aircraft applications, where high performance is of primary importance. Another development in this area is the incorporation of boron filaments in metal matrices.

The use of boron has found its way in such diversified applications as in motor-starting devices, phonograph needles, lightning arresters, thermal cutouts for transformers, igniters in rectifier and control tubes, alloys resistant to high-temperature abrasion and scaling, constant-potential controllers, thermoelectric couples, and resistance thermometers.

Certain compounds of boron, such as borax and boric acid, have been known and used for a long time in glass, enamel, ceramic, and mining industries. Refined borax, Na₂B₄O₇·H₂O, is an important ingredient of a variety of detergents, soaps, water-softening compounds, laundry starches, adhesives, toiletry preparations, cosmetics, talcum powder, and glazed paper. It is also used in fireproofing, disinfecting of fruit and lumber, weed control, and insecticides, as well in the manufacture of leather, paper, and plastics.

BMC

See *bulk molding compound*.

BMI

See *bismaleimide*.

Board Hammer

A type of forging hammer in which the upper die and ram are attached to “boards” that are raised to the striking position by power-driven rollers and let fall by gravity. See also *gravity hammer*.

Boat

A box or container used to hold the green powder metallurgy compacts during passage through a continuous sintering furnace.

B**Body**

(1) A loosely used term designating viscosity or consistency. (2) The consistency of an adhesive, which is a function of viscosity, plasticity, and rheological factors.

Body Putty

A pastelike mixture of plastic resin (polyester or epoxy) and talc used in repair of metal surfaces, such as auto bodies.

Body-Centered

Having an atom or group of atoms separated by a translation of $1/2$, $1/2$, $1/2$ from a similar atom or group of atoms. The number of atoms in a body-centered cell must be a multiple of 2.

Body-Centered Cubic

A crystal lattice structure with an atom at the center and corners of the unit cube.

Bohr Atom

This regards an atom as a central nucleus with electrons and fixed orbits around it.

Boiler

A vessel or system of vessels and pipework in which water is boiled to produce steam. In many cases, the system will be under pressure thereby raising the boiling point considerably; 350°C is not uncommon for steam for power plant.

Boiler Plate

An imprecise term usually indicating a good-quality mild steel, typically 0.12–0.2 carbon, less than 1% manganese, and probably in the normalized condition.

Boiler Scale

An imprecise term usually referring to the deposits of calcium sulfate, possibly intermixed with magnetite, found on the water side of boiler circuits evaporating poor-quality water. The term has occasionally been used regarding the scale and deposits on the fireside of tubes.

Boiler Tube

The tubes in which water is heated to form steam in a boiler, as opposed to superheater tubes in which the steam is further heated. In a fire tube boiler, the flame and combustion products pass through the tubes that are immersed in the water. In a water tube boiler, the water is contained in the tubes that pass through the combustion chamber or, usually, form the wall of the combustion chamber, hence the term waterwall tubes.

Boiling

The vigorous evolution of bubbles as a fluid changes to a gas.

Bolster

(1) A plate to which dies may be fastened, the assembly being secured to the top surface of a press bed. In press forging, such a plate may also be attached to the ram.

Bolt

A threaded fastener having a head at one end, a threaded length at the other, and a plain shank between. Bright bolts are normally machined all over. The term black mold originally referred to bolts that were at least partially covered with a black scale; nowadays, the term usually indicates not color but a bolt with wider machining tolerances than a bright bolt.

Boltzmann Constant

The gas constant divided by Avogadro's number, 1.380×10^{-23} J/K.

Boltzmann Distribution

In materials characterization, a function giving the probability that a molecule of a gas in thermal equilibrium will have generalized position and momentum coordinates within a given infinitesimal range of values.

Bond

(1) In grinding wheels and other relatively rigid abrasive products, the material that holds the abrasive grains together. (2) In welding, brazing, or soldering, the junction of joined parts. Where filler metal is used, it is the junction of the fused metal and heat-affected base metal. (3) In an adhesive bonded or diffusion bonded joint, the line along which the faying surfaces are joined together. (4) In thermal spraying, the junction between the material deposited and the substrate, or strength. See also *adhesive bond*, *mechanical bond*, and *metallic bond*.

Bond Angle

The angle formed by the bonds of one atom to other atoms, for example, 109.5° for C–C bonds.

Bond Clay

Any clay suitable for use as a *bonding agent* in molding sand.

Bond Coat (Thermal Spraying)

A preliminary (or prime) coat of material that improves adherence of the subsequent thermal spray deposit.

Bond Face

The part or surface of an adherend that serves as a substrate for an adhesive.

Bond Length

The average distance between the centers of two atoms, for example, 0.154 nm ($1.54 \text{ \AA}$) for C–C bonds.

Bond Line

The cross section of the interface between thermal spray deposits and substrate, or the interface between an adhesive and an adherend in an adhesive bonded joint.

Bond Strength

(1) The unit load applied to tension, compression, flexure, peel, impact, cleavage, or shear required to break an adhesive assembly with failure occurring in or near the plane of the bond. The term *adherence* is frequently used in place of bond strength. (2) The force required to pull a coating free of a substrate. (3) The degree of cohesiveness that the *bonding agent* exhibits in holding sand grains together.

Bonded Film Lubricant

See *bonded solid lubricant*.

Bonded Solid Lubricant

A solid lubricant dispersed in a continuous matrix of a binder, or attached to a surface by an adhesive material.

Bonded-Phase Chromatography (BPC)

Liquid chromatography with a surface-reacted, that is, chemically bonded, organic stationary phase. See also *normal phase chromatography* and *reversed-phase chromatography*.

Bonderizing

A process for producing phosphate conversion coatings on steel components by immersion in a hot acid solution of zinc and manganese phosphates. The coatings improve corrosion resistance and paint adhesion and provide lubrication during drawing.

Bonding

A method of holding the parts of an object together with or without the aid of an adhesive such as an epoxy or glue. Composite materials such as fiber-reinforced plastics require strong interfacial bonding between the reinforcement and the matrix. In the case of atomic or optical contact bonding, interatomic forces hold the parts together. An optical contact bonding, surface flatness, and cleanliness between the mating parts determine the bonding strength, and the atoms at the surface provide the necessary forces. The number of valence electrons in the atoms of a material determines the bonding strength between the group of atoms that constitutes a molecule. In these cases, the term *chemical bonding* is used.

Wire bonding as an interconnect technique widely used in microchip manufacturing to provide electrical continuity between the metal pads of an integrated circuit chip and the electrical leads of the package housing the chip. The two common methods of wire bonding are thermocompression and ultrasonic bonding. In these, a fine aluminum or gold wire is bonded at one end to the metal pad of the integrated circuit chip and at the other to the electrical lead of the package. There are three types of

thermocompression bonds: wedge, stitch, and ball. In thermocompression bonding, a molecular metallurgical bond is formed at the two metal junctions—bond wire and IC metal pad and bond wire and package lead metal—by applying heat and pressure without melting. In ultrasonic bonding, the molecular metallurgical bond is achieved through a combination of ultrasonic energy and pressure. The bonding operation is done under pressure to break the few surface layers of the material and form the bond between the contamination-free surfaces. Thermocompression bonding has higher throughput and speed than ultrasonic bonding. The bonding wire is usually aluminum, which does not introduce any intermetallic problems.

Bonding Agent

Any material other than water that, when added to foundry sands, imparts strength in either the green, dry, or fired state.

Bonding Force

The force that holds two atoms together; it results from a decrease in energy as to atoms are brought closer to one another.

Bonding Materials

These are matrix materials in glass-fiber-reinforced plastics whereby the fiber glass reinforcement has been previously sized and supplied with these polymeric materials, which are catalysts, accelerators, fillers, inhibitors, and plasticizers.

- *Acrylic polymers*: Limited use as a laminating resin in the form of thermosetting acrylic syrup to make glazing panels. The monomer is used in conjunction with styrene as a cross-linking agent in polyesters to improve weathering resistance.
- *Alkyds*: Reaction products of polymerization of polyhydroxy alcohols and polycarboxylic acids, such as glycerol and phthalic anhydride. Modified grades are reinforced by glass fibers in chopped strand form.
- *Epoxy resins*: Reaction products of bisphenol A and epichlorohydrin. Epoxies are cross-linked by the addition of acids or amines to form laminating resins of exceptional bonding properties. These boast excellent electrical properties and high resistance to acids and alkalis and are used with fiberglass cloth and strands.
- *Melamine formaldehyde*: Melamine reacts with 1–6 mol of formaldehyde to form various compounds with good electrical characteristics. Used in flat electrical laminates, reinforced by glass cloth, these resins also are used for bonding glass fibers and thermal insulation.
- *Phenol formaldehyde resins*: Condensation polymerization products of phenol and formaldehyde are used primarily for bonding fiberglass insulation products. Also used in flat fiberglass cloth laminates for electrical applications.
- *Polyesters*: Unsaturated polyester resins are made by condensation polymerization of polyfunctional acids such as maleic acid and phthalic anhydride of cross-linking agents such as styrene. These represent the largest family of resins used in laminating and molding fiberglass cloth and strands.

B**Bone Oil**

A fatty oil obtained by dry distillation of bones.

Book Mold

A split permanent mold hinged along one edge to open like a book.

Borate Glass

A glass in which the essential glass former is boron oxide instead of silica. See also *glass*.

Borax

A white or colorless crystalline mineral used in glass and ceramic and enamel mixes, as a scouring and cleansing agent, as a flux in melting metals and in soldering, brazing, and welding (it forms a hard glassy deposit on cooling), as a corrosion inhibitor in antifreeze liquids, as a constituent in fertilizers, in the production of many chemicals and pharmaceuticals, and as a source of boron. Borax is a hydrous sodium borate, or tetraborate.

Bore

(1) The hollow space within a tube or a similar vessel. (2) The internal diameter as a dimension, or the internal surface of a tube, gun, etc. (3) A hole or cylindrical cavity produced by a single-point or multipoint tool other than a drill.

Bore Seal

A device in which the outside diameter mates with a bore surface to provide sealing between the two surfaces.

Boriding

Thermochemical treatment involving the enrichment of the surface layer of an object with borides. This surface-hardening process is performed below the A_1 temperature. Also referred to as boronizing.

Boring

Enlarging a hole by removing metal with a single- or occasionally a multiple-point cutting tool moving parallel to the axis of rotation of the work or tool.

Boron

Boron (B) is a metallic element closely resembling silicon. Boron has a specific gravity of 2.31, with a melting point of about 2200°C, and a Knoop hardness of 2700–3200, equal to a Mohs hardness of about 9.3. At 600°C, boron ignites and burns with a brilliant green flame. Minute quantities of boron are used in steels for case hardening by the nitriding process to form boron nitride and in other steels to increase hardenability, or depth of hardness. In these boron steels, as little as 0.003% is beneficial, forming an iron boride, but with larger amounts, the steel becomes brittle and susceptible to being hot-short unless it contains titanium or some other element to stabilize the carbon. In cast iron, boron inhibits

graph-atomization and also serves as a deoxidizer. It is added to iron and steel in the form of ferroboron.

Boriding, diffusing boron into metal surfaces, forms intermetallics that increase hardness, thus wear resistance. It can also improve corrosion resistance and the bonding and brazing of certain alloys. Boron diffusion can increase the surface hardness of ferrous alloys to 1500–1700 Knoop and their resistance to hydrochloric, hydrofluoric, and sulfuric acids. Resistance to attack by these acids also pertains to nickel alloys. For nickel- or cobalt-bonded tungsten carbide and titanium carbide, boron diffusion can markedly increase erosion resistance.

The free element is prepared in crystalline or amorphous form. The crystalline form is an extremely hard, brittle solid. It is jet-black to silvery-gray color with a metallic luster. One form of crystalline boron is bright red. The amorphous form is less dense than the crystalline and is a dark brown to black powder.

Crystalline boron, although relatively brittle compared to diamond, is second only to diamond and hardness.

The chemical properties of boron depend largely on the physical form as well as all of the purity of samples. Amorphous boron oxidizes slowly in the air even at room temperature and is spontaneously flammable at about 860°C.

Boron is not affected by either hydrochloric or hydrofluoric acids, even on prolonged boiling. Crystalline boron is quite stable to heat and oxidation even at relatively high temperatures. It is slowly attacked and oxidized by hot concentrated nitric acid and by mixtures of sodium dichromate and sulfuric acid. Hydrogen peroxide and ammonium persulfate also slowly oxidize crystalline boron.

All varieties of boron are completely oxidized by molten mixtures of alkali carbonates and hydroxides.

Boron reacts vigorously with sulfur at about 600°C to form a mixture of boron sulfides. Boron nitride is formed when boron is heated in a N_2 or NH_3 atmosphere above 1000°C. At high temperatures, boron combines with phosphorus and with arsenic to form a phosphide, BP, and an arsenide, BAs.

It reacts with silicon to form silicon borides at temperatures above 2000°C.

Boron reacts with the majority of metals and metal oxides at high temperatures to form metallic borides. Boron does not conform to the usual rules of valence in forming these compounds. The borides, along with the carbides and the nitrides, are called interstitial compounds. These compounds have crystal structures and properties very similar to those of the original metal.

Metallic borides are usually prepared by hot sintering of the elements. They may also be prepared by carbothermic and aluminothermic reduction of metal oxide–boron oxide mixtures. A number of metallic borides of high purity have been prepared on a semi-commercial scale by vapor deposition methods, in which the volatile halides of the elements are deposited on a hot substrate, such as tungsten or tantalum wire, in an atmosphere of H_2 . Borides have much in common with true metals. They have a high electrical conductivity, high melting points, and extreme hardness. Many metal borides are used as components of cermet compositions.

Boron fibers for reinforced structural composites are continuous fine filaments that are, themselves, composites. They are produced by vapor deposition of boron on a tungsten or carbon substrate. Their specific gravity is about 2.6, and they range from 0.10 to 0.15 mm in diameter. They have tensile strengths around 3450 MPa and a modulus of elasticity of nearly 0.5 million MPa. The fibers are used chiefly in aluminum or epoxy matrixes. Unidirectional boron–aluminum composites have tensile strengths ranging from 758 to over 1378 MPa. Their strength-to-weight ratio is about three times greater than that of high-strength aluminum alloys.

Boron compounds are employed for fluxes and deoxidizing agents and melting metals and for making special glasses. Boron, like silicon and carbon, has an immense capacity for forming compounds, although it has a different valence. The boron atom appears to have a lenticular shape, and two boron atoms can make a strong electromagnetic bond, with the boron acting like carbon but with a double ring.

Boron Carbide

Boron carbide (B_4C) is produced by the high-temperature (about $1371^{\circ}C$ – $2482^{\circ}C$) interaction of boric oxide, B_2O_3 , and carbon in an electrical resistance-type furnace. It is a black, lustrous solid. It is used extensively as an abrasive because its hardness approaches that of the diamond. It is also used as an alloying agent, particularly in molybdenum steels.

Additionally, it is used in drawing dies and gauges, or into heat-resistant parts such as nozzles. The composition is either B_6C or B_4C ; the former is the harder but usually contains an excess of graphite difficult to separate in the powder. It can be used thus as a deoxidizing agent for casting copper and also for lapping, since the graphite acts as a lubricant. Boroflux is B_4C with flake graphite, used as a casting flux.

B_4C parts are fabricated by hot pressing, sintering, and sinter-HIPing (hot isostatic press [HIP]). Industrially, densification is carried out by hot pressing ($2100^{\circ}C$ – $2200^{\circ}C$, 20–40 MPa) in argon. The best properties are obtained when pure fine powder is densified without additives. Pressureless sintering to high density is possible using ultrafine powder, with additives (notably carbon). Less expensive than hot pressing, sintering also can be used for more complex shapes.

Special part formulations include bonding B_4C with fused sodium silicate, borate frits, glasses, plastics, or rubbers to lend strength, hardness, or abrasion resistance. B_4C -based cermets and MMC (especially Al/B_4C , Mg/B_4C , Ti/B_4C) and CMCs (e.g., TiB_2/B_4C) have unique properties, including superior ballistic performance, that make these materials suitable for highly specialized applications. High-temperature strength, light weight, corrosion resistance, and hardness make these composites especially attractive. B_4C shapes can be reaction-bonded using SiC as the bonding phase. B_4C –C mixtures are formed and then reacted with silicon to create the SiC bond. SiC also can be used as a sintering aid for B_4C and vice versa.

As an abrasive, B_4C is used for fine polishing and ultrasonic grinding and drilling, either as a loose powder or as a slurry. Its tendency to oxidize at workpiece temperatures precludes its use in bonded abrasive wheels. Abrasion-resistant parts made from B_4C include spray and blasting nozzles, bearing liners, and furnace parts. The refractory properties of B_4C , in addition to its abrasion resistance, are of value in the latter application.

B_4C is chemically inert, although it reacts with O_2 at elevated temperatures and with white hot or molten metals of the iron group and certain transition metals. B_4C reacts with halogens to form boron halides—precursors for the manufacture of most nonoxide boron chemicals. B_4C also is used in some reaction schemes to produce transition metal borides. Boronizing packings containing B_4C are used to form hard boride surface layers on metal parts.

B_4C and elemental boron are used for nuclear reactor control elements, radiation shields, and moderators.

B_4C platelets are single crystals of B_4C or $B_{13}C_2$ that are of 1–5 mm average diameter and about 0.2 mm thick. The tiny B_4C platelets have proved to be highly effective in reinforcing ceramic materials. Toughness values of $8.1 \text{ MPa m}^{1/2}$ have been reported in

B_4C platelet-reinforced Al_2O_3 with corresponding four-point bed strengths of more than 650 MPa.

Boron Nitride

Boron nitride (BN) has many potential commercial applications. It is a white, fluffy powder with a greasy feel. It has an x-ray diffraction pattern almost identical with that of graphite, indicating a close similarity in structure. It is called white graphite. BN has a very low coefficient of friction, but unlike carbon, it is a nonconductor of electricity, and it is attacked by nitric acid. It sublimates at $3000^{\circ}C$. It reacts with carbon at about $2000^{\circ}C$ to form boron carbide (B_4C). It is used for heat-resistant parts by molding and pressing the powder without a binder to a specific gravity of 2.1–2.25.

BN may be prepared in a variety of ways, for example, by the reaction of boron oxide with ammonia, alkali cyanides, and ammonium chloride, or of boron halides and ammonia. The usually high chemical and thermal stability, combined with high electrical resistance of BN, suggests numerous uses for this compound in the field of high-temperature technology. BN can be hot-pressed into molds and worked into desired shapes.

BN uses include as a lubricant for high-pressure bearings, for compacting into mechanical and electrical parts, and as an additive to plastics, potting compounds, oils, and grease to increase thermal conductivity and dielectric strength. Not wetted by and highly resistant to many molten metals and slags, it is used as a release agent and container material for molten salts, various metals, and nonlead glasses and for braze stop-off and weld-splatter release coatings.

BN powders can be used as mold-release agents, high-temperature lubricants, and additives in oils, rubbers, and epoxies to improve thermal conductance of dielectric compounds. Powders also are used in metal–matrix and ceramic–matrix composites (MMC and CMC) to improve thermal shock and to modify wetting characteristics.

Hexagonal BN may be hot-pressed into soft (Mohs 2) and easily machinable white or ivory billets having densities 90%–95% of theoretical (2.25 g/cm^3). Thermal conductivities of 17–58 W/m K and coefficients of thermal expansion of 0.4 – $5 \times 10^{-6}/^{\circ}C$ are obtained, depending on density, orientation with respect to pressing direction, and amount of boric oxide binder phase. Because of its porosity and relatively low elastic modulus (50–75 GPa), hot-pressed BN has outstanding thermal shock resistance and fair toughness. Pyrolytic BN, produced by chemical vapor deposition (CVD) on heated substrates, also is hexagonal; the process is used to produce coatings and shapes with thin cross sections.

Uses for hexagonal BN shapes include crucibles, parts for chemical and vacuum equipment, metal casting fixtures, boron sources for semiconductor processing, and transistor mounts.

A cubic form of BN, called borazon, has been prepared at pressures near 6500 MPa and temperatures near $1500^{\circ}C$. It is comparable to diamond in hardness and apparently has properties superior to those of diamond with regard to oxidation, electrical resistance, and thermal stability. This material will probably take its place with diamond for industrial grinding. Borazon is stable up to about $1925^{\circ}C$. This molded material is resistant to molten aluminum, is not wetted by molten silicon or glass, and is used for crucibles. Cubic BN tooling typically outlasts Al_2O_3 and carbide tooling and is preferred in applications where diamond is not appropriate, such as grinding of ferrous metals.

BN fibers are produced in diameters as small as 5–7 μm and in lengths to 0.38 m. The fibers have a tensile strength of 1378 MPa. They are used for filters for hot chemicals and as reinforcement to plastic lamination. BN HCl is a fine powder, 99% pure, and is used

B

as a filler in encapsulating and potting compounds to add thermal and electric conductivity. BN is basically the same as B_4C and can only be densified by hot pressing. Hot-pressed hexagonal BN is easy to machine and has a low density but must be kept free of boron oxide (or the boron oxide stabilized with CaO-containing additives), so BN is not destroyed by hydration during heating.

A tough, coherent, hard abrasive compact, consisting of a cubic form of the end bonded with B_4C , has been developed.

Boronizing

See *boriding*.

Borosilicate Glass

Any silicate glass having at least 5% of boron oxide (B_2O_3). See also *glass*.

Bort

(1) Natural diamond of a quality not suitable for gem use. (2) Industrial diamond.

Bosh

(1) The section of a blast furnace extending upward from the tuyeres to the plane of maximum diameter. (2) A lining of quartz that builds up during the smelting of copper ores and that decreases the diameter of the furnace at the tuyeres. (3) A tank, often with sloping sides, used for washing metal parts or for holding cleaned parts.

Boss

(1) A relatively short protrusion or projection from the surface of a forging or casting, often cylindrical in shape. Usually intended for drilling and tapping for attaching parts. (2) Projection on a plastic part designed to add strength, to facilitate alignment during assembly, or to provide for a fastening. (3) A raised area or reinforcement. It might, for example, act as a location, support point, or be drilled to act as a bearing.

Bottle

A partly pierced billet. See preferred term *cylinder*.

Bottle Bored

A bored forging with the chamber at some position along the bore. Large forgings for high-speed rotors for turbine generators, and similar applications are bored axially along their centerline to remove the poor-quality material remaining from the original ingot. In some cases, defects extend deeper than the, typically 100 mm diameter, bore. In such cases, a short length is machined deeper to cut out the defects forming a chamber or bottle, provided that the design can accommodate the variation.

Bottom Blow

A specific type of *blow molding* technique for plastics that forms hollow arteries by injecting the blowing air into the parison from the bottom of the mold (as opposed to introducing the blowing air at a container opening).

Bottom Board

In casting, a flat base for holding the *flask* in making sand molds.

Bottom Draft

Slope or taper in the bottom of a forge depression that tends to assist metal flow toward the sides of depressed areas.

Bottom Drill

A flat-ended twist drill used to convert a cone at the bottom of a drilled hole into a cylinder.

Bottom Pipe

An oxide-lined fold or cavity at the butt end of a slab, bloom, or billet; formed by folding the end of an ingot over on itself doing primary rolling. Bottom pipe is not *pipe*, in that it is not a shrinkage cavity, and in that sense, the term is a misnomer. Bottom pipe is similar to *extrusion pipe*. It is normally discarded when the slab, bloom, or billet is cropped following primary reduction.

Bottom Plate

In making of plastic parts, the part of the mold that contains the heel radius and the push-up.

Bottom Punch

In powder metallurgy, the part of the tool assembly that closes the die cavity at the bottom and transfers the pressure to the powder during compaction.

Bottom Running or Pouring

Filling of the casting mold cavity from the bottom by means of gates from the runner.

Bottom-End Bearing

See *big-end bearing*.

Bottoming Bending

Press-brake bending process in which the upper die (punch) enters the lower die and coins or sets the material to eliminate *spring back*.

Bottoming Tap

A tap with a chamfer of 1–1½ threads in length.

Bottom-Pour Ladle

A *ladle* from which metal, usually steel, flows through a *nozzle* located at the bottom.

Boundary Lubricant

A lubricant suitable for use in *boundary lubrication* conditions. Fatty acids and soaps are commonly used.

Boundary Lubrication

A condition of lubrication in which the friction and wear between two surfaces in relative motion are determined by the properties of the surfaces and by the properties of the lubricant other than bulk viscosity. The thin film of lubricant may be possibly only a molecule thick. See also the term *lubrication regimes*.

Bow

(1) A condition of longitudinal curvature in protruded plastic parts. (2) The tendency of material to curl downward during shearing, particularly when shearing long narrow strips.

Bowing

Deviation from flatness.

Box Annealing

Annealing a metal or alloy in a sealed container under conditions that minimize oxidation. In box annealing a ferrous alloy, the charges are usually heated slowly to a temperature below the transformation range, but sometimes above or within it, and are then cooled slowly; this process is also called close annealing or pot annealing. See also *black annealing*.

Box Furnace

A furnace used for batch sintering of powder metallurgy parts, normally utilizing a controlled atmosphere-containing sealed retort.

Boxing

The continuation of a fillet weld around a corner of a member as an extension of the principal weld.

Brackish Water

(1) Water having salinity values ranging from approximately 0.5 to 17 parts per thousand. (2) Water having less salt than seawater, but undrinkable.

Bragg Angle

The angle between the incident beam and the lattice planes considered.

Bragg Equation

See *Bragg's law*.

Bragg Method

A method of x-ray diffraction in which a single crystal is mounted on a spectrometer with a crystal face parallel to the axis of the instrument.

Bragg's Law

A statement of the conditions under which a crystal will diffract electromagnetic radiation. Bragg's law reads $n\lambda = 2d \sin \theta$, where n is

the order of reflection, λ is the wavelength of x-rays, d is a distance between lattice planes, and θ is the Bragg angle, or the angular distance between the incident beam and the lattice planes considered.

Braiding

Intertwining two or more systems of yarns in the bias direction to form an integrated structure.

Brake

A device for bending sheet metal to a desired angle.

Brale

A diamond 120° indenter, of conical form with a hemispherical tip, used on the Rockwell hardness testing machine for testing hard materials. A 0.2 mm tip radius is typical.

Branched Polymer

In the molecular structure of polymers, a main chain with attached side chains, in contrast to a linear polymer. Two general types are recognized, short-chain and long-chain branching.

Branching

The presence of molecular branches in a polymer. The generation of branch crystals during the crystallization of a polymer.

Brass

Brass is an alloy of copper and zinc. In the manufacture, lump zinc is added to molten copper, and the mixture is poured either into castings ready for use or into billets for further working by rolling, extruding, forging, or a similar process. Brasses containing 75%–85% copper are red gold and malleable; those containing 60%–70% are yellow and also malleable; and those containing 50% or less copper are white, brittle, and not malleable.

Copper–zinc alloys whose zinc content ranges up to 40% with the copper crystal structure face-centered cubic (fcc) are considered brass. This solid solution alpha brass has good mechanical properties, combining strengths with ductility. Corrosion resistance is very good, but electrical conductivity is considerably lower than for copper.

Beta brass contains nearly equal proportions of copper and zinc. Specific brasses are designated as follows: gilding (95% copper; 5% zinc), red (85:15), low (80:20), and Admiralty (70:29, with balance of tin). Naval brass is 59%–62% copper, with about 1% tin, less than that of lead and iron, and the remainder zinc. With small amounts of other metals, other names are used: commercial bronze (10% zinc), jewelry bronze (12% zinc), red brass (15% zinc), yellow brass (35% zinc), and Muntz metal (40% zinc). As the zinc content increases in these alloys, the melting point, density, electric and thermal conductivity, and modulus of elasticity decrease while the coefficient of expansion, strength, and hardness increase. Work hardening also increases with zinc content. These brasses have a pleasing color, ranging from the rate of copper for the low-zinc alloys through bronze and gold colors to the yellow of high-zinc brasses. The color of jewelry bronze closely matches that of 14-karat gold, and this alloy and other low brasses are used in inexpensive jewelry.

B

The low-zinc brasses have good corrosion resistance along with moderate strength and good forming properties. Red brass, with its exceptionally high corrosion resistance, is widely used for condenser tubing. The high brasses (cartridge brass and yellow brass) have excellent ductility and high strength and are widely used for engineering and decorative parts fabricated by drawing, stamping, cold heading, spinning, and etching. Muntz metal, primarily a hot-working alloy, is used where cold working is not required.

Leaded brass is used for castings. These alloys have essentially the same range of zinc content as the straight brasses. Lead is present, ranging from less than 1% to 3.25%, to improve machinability and related operations. Lead also improves antifriction and bearing properties.

Another group, the tin brasses, is copper–zinc alloys with small amounts of tin. The tin improves corrosion resistance. Pleasing colors are also obtained when tin is added to the low brasses. Tin brasses and sheet and strip form, with 80% or more copper, are used widely as low-cost spring materials. Admiralty brass is a standard alloy for heat exchanger and condenser tubing. Naval brass and manganese bronze are widely used for products requiring good corrosion resistance and high strength, particularly in marine equipment.

Casting brasses are usually made from brass ingot metal and are medium plain copper–zinc alloys. In melting brass for casting, any superheating causes loss of zinc by vaporization, thus lowering the zinc amount. Small amounts of antimony or some arsenic are used to overcome this dezincification. The casting brass is roughly divided into two classes, *red casting brass* and *yellow casting brass*, which are various compositions of copper, tin, zinc, and lead to obtain the required balance of color, ease of casting, hardness, and machining qualities. *Copper–bismuth–selenium alloys*, C89510, C89520, and C89550, are lead-free or low-lead alternatives to lead-bearing red and yellow brasses, thereby meeting low-lead leach requirements of regulatory agencies for potable-water plumbing fixtures. The alloys are also called *EnviroBrass I, II, and III*, respectively, and because of their selenium and bismuth contents, *SeBilloys*.

Many brasses are now designated by alloy number and grouped into several families of standard alloys. There are three families of wrought brass: *copper–zinc brasses* (C20500–C28580); *copper–zinc–lead brasses*, or *leaded brasses* (C31200–C38590); and *copper–zinc–tin brasses*, or tin brasses (C40400–C49080). Casting alloys comprise four families: *copper–tin–zinc red brasses* and *copper–tin–zinc–lead brasses*, or *leaded red brasses* (C83300–C83810); *copper–zinc–tin–lead brasses*, *semired brasses*, and *leaded semired brasses* (C84200–C84800); *copper–zinc–lead–tin yellow brasses*, and *manganese-bearing high-strength yellow brasses* (C85200–C85800); and *copper–zinc–silicon brasses*, or *silicon brasses* (C87300–C87900). Wrought alloys are available in most mill forms, and casting alloys are amenable to most casting processes, including sand, permanent mold, investment, plaster, and centrifugal. A few alloys can be die-cast.

The mechanical properties of brasses vary widely. Strength and hardness depend on alloying and/or cold work. Tensile strengths of annealed grades are as low as 206 MPa, although some hard tempers approach 620 MPa.

Brass is annealed for drawing and bending by quenching in water from a temperature of about 538°C. Simple copper–zinc brasses are made in standard degrees of temper, or hardness. This hardness is obtained by cold rolling after the first anneal, and the degree of hardness depends on the percentage of cold reduction. When the thickness is reduced about 10.9%, the resulting sheet is 1/4 hard. The other grades are 1/2 hard, hard, extra hard, spring, and finally extra spring, which corresponds to a reduction of about 68.7% without intermediate annealing. Degrees of softness and annealed brass are

measured by the grain size, and annealed brass is furnished in grain sizes from 0.010 to 0.150 mm.

Even slight additions of other elements to brass alter characteristics drastically. Slight additions of tin change the structure, increasing the hardness but reducing the ductility. Iron hardens the alloy and reduces the grain size, making it more suitable for forging but making it difficult to machine. Manganese increases strength, increases the solubility of iron in the alloy, and promotes stabilization of aluminum, but makes the brass extremely hard. Slight additions of silicon increase strength, but large amounts promote brittleness, loss of strength, and danger of oxide inclusion. Nickel increases strength and toughness, but when any silicon is present, the brass becomes extremely hard and more a bronze than a brass.

Brasses widely used in cartridge cases, plumbing fixtures, valves and pipes, screws, clocks, and musical instruments.

Brass Ingot Metal

Commercial ingots made in standard composition grades and employed for casting various articles designated as brass and bronze. They are seldom true brasses, but are composition metals intermediate between the brasses and the bronzes and their selection for any given purpose are based on a balance of the requirements in color, strength, hardness, ease of casting, and machinability. Brass ingot metal is usually made from secondary metals, but, in general, the grading is now so good that they will produce high-grade uniform castings. In producing the ingot metal, there is careful sorting of the scrap metals, and the impurities are removed by remeltings. An advantage of ingot metal over virgin metals is the ease of controlling mixtures in the foundry. The ATSM designates eight grades for brass ingot metal. Number 1 grade, the highest in copper, contains 88% copper, 6.5% zinc, 1.5% lead, and 4% tin, with only slight percentages of impurities. The No. 8 grade contains 63.5% copper, 34% zinc, 2.5% lead, and no tin. *Yellow ingot*, for plumbing fixtures, contains 65% copper, 1% tin, 2% lead, and the balance zinc. The most widely used ingot metal is *ASTM alloy No. 2*, which is the 85:5:5:5 alloy known as *composition metal*. Yellow brass, or *yellow casting brass*, is frequently cast from *ASTM alloy No. 6*, which contained 72% copper, 22% zinc, 4% lead, and 2% tin. It has a tensile strength of 138–172 MPa, elongation 15%–20%, and Brinell hardness 40–50. It is yellow and makes clean, dense castings suitable for various machine parts except bearings.

Braze

A joining process in which a metal is melted and applied to the interface between two components that are not melted in the process. It is implicit that the braze material has a composition different from, and a melting point lower than, those of the components being joined. The braze metal, sometimes termed the filler (metal), melts and bonds to the two components producing a strong joint. Use of the term is normally confined to joints where the interface to be joined is narrow but of large area relative to the cross section and where the molten filler is either drawn into the interface by capillary action or introduced as a preplaced strip or sleeve prior to heating. If this restriction is recognized, then joints made with bulky deposits of lower melting point filler metal are termed braze welds. Originally brazing referred to the use of brass to join copper or steel and it is still widely used in this narrow sense. However, the term is now applied to any joint meeting the aforementioned general description where the filler material melting range exceeds about 450°C. For example, aluminum may be brazed with a lower melting

point of aluminum–silicon alloy. Where the filler melting range is below about 450°C, the process is normally termed soldering or soft soldering. In most brazing processes, a flux or other means of cleaning the component surfaces is required. Many processes are used including gas or flame brazing, furnace brazing, bath or dip brazing, and vacuum and induction brazing, the various terms indicating the heat source or the environment. The term hard soldering means brazing or silver soldering.

Braze Interface

See *weld interface*.

Braze Welding

A method of welding by using a filler metal having a liquidus above 450°C (840°F) and below the solidus of the base metals. Unlike *brazing*, in braze welding, the filler metal is not distributed in the joint by capillary action.

Brazeability

The capacity of a metal to be brazed under the fabrication conditions imposed into a specific suitably designed structure and to perform satisfactorily in the intended service.

Brazement

An assembly whose component parts are joined by brazing.

Brazing

A group of welding processes that join solid materials together by heating them to a suitable temperature and using a filler metal having a liquidus above 450°C (840°F) and below the solidus of the base materials. The filler metal is distributed between the closely fitted surfaces of the joint by capillary action.

Brazing provides advantages over other welding processes, especially because it permits joining of dissimilar metals that, because of metallurgical incompatibilities, cannot be joined by traditional fusion processes. Since base metals do not have to be melted to be joined, it does not matter that they have widely different melting points. Therefore, steel can be brazed to copper as easily as steel to steel.

Brazing also generally produces less thermally induced distortion (warping) than fusion welding does, because an entire part can be brought up to the same brazing temperature, thereby preventing the kind of localized heating that can cause distortion in welding.

Finally, and perhaps most important to the manufacturing specialist, brazing readily lends itself to mass-production techniques.

The important elements of the brazing process are filler-metal flow, base-metal and filler-metal characteristics, surface preparation, joint design and clearance, and temperature, time, rate, and source of heating.

A myriad of applications of brazing occur in many fields, including automotive and aircraft designs; engines and engine components; electron tubes; vacuum equipment and nuclear components, such as production of reliable ceramic-to-metal joints; and miscellaneous applications such as fabrication of food-service dispensers (scoops) used for ice cream and corrosion-resistant and leak-proof joints in stainless steel blood-cell washers.

Brazing Alloy

See preferred term *brazing filler metal*.

Brazing Filler Metal

(1) The metal that fills the capillary gap and introduced into the brazed joint (see *braze*) to form the bond between the two components. It has a liquidus above 450°C (840°F) but below the solidus of the base materials. (2) A nonferrous filler metal used in *brazing and braze welding*. (3) The composition of the filler metal depends on the materials being joined, but for steels and copper alloys, typical filler metals include phosphor–copper, various plain or complex brasses, and silver solders.

A common name for high-copper brass used for the casting of such articles as flanges that are to be brazed on copper pipe. Federal specifications for brazing metal call for 84%–86% copper and the balance zinc. *Brazing brass*, of the American Brass Co., has 75% copper and 25% zinc. Some alloys also contain up to 3% lead for ease of machining. It also makes the metal easier to cast. *Nickel welding rod* is often used to braze cast iron. So is *nickel silver* containing 46.3% copper, 43.4% zinc, 10% nickel, 0.1% silicon, and 0.02% phosphorous, which matches the color of cast iron.

The term “brazing metal” is also applied to *brazing rods* of brass or bronze, used for joining metals. A common brazing rod is the 50–50 brass alloy with a melting point of 1616°F (880°C). The SAE designates this alloy as *spelter solder*. The joints made with it are inclined to be brittle. *Brazing wire*, of Chase Brass and Copper Co., contains 59% copper and 41% zinc, while the *brazing solder*, for brazing high-zinc brasses, has 51% copper and 49% zinc. *Phos-copper* is a phosphor copper that gives joints 98% the electric conductivity of copper. It flows at 1382°F (750°C). *Trimetal* is a brazing metal consisting of sheet brass with a layer of silver rolled on each side. It is used for brazing carbide tips to steel tools. The silver ensures a tightly brazed joint, while the brass center acts as a shock absorber for the cutting tool.

Brazing rods for brazing brasses and bronzes are usually of a composition similar to that of the base metal. For brazing cast iron and steel, various bronzes, naval brass, manganese bronze, or silicon bronze may be used. Brass rods may contain some silicon. Small amounts of silver added to the high-copper brazing metals give greater fluidity and better penetration into small openings. Because of the toxicity of *cadmium*, cadmium-free brazing filler materials such as the silver–copper–zinc *BAG-5*, *BAG-6*, *BAG-20*, and *BAG-35 brazing filler metals* and silver–copper–zinc–tin *BAG-7*, *BAG-28*, *BAG-34*, *BAG-36*, and *BAG-37 brazing filler metals* have been developed as alternatives. For joining *tungsten carbide* tips to steel, silver–copper–zinc–nickel *BAG-4* and *BAG-24 brazing filler metals* are alternatives. For joining copper and copper alloys, there are the copper–phosphorus *BCuP-2*, *BCuP-3*, *BCuP-4*, *BCuP-5*, *BCuP-6*, and *BCuP-7 brazing filler metals* and silver–copper–phosphorus brazing filler metals, both of which are self-fluxing on copper-to-copper metals. With a brazing flux they also can braze brasses and bronzes. However, they should not be used to braze iron or nickel alloys, or copper alloys if the nickel content exceeds 10%.

Microbraz alloys, from Wall Colmonoy, are nickel-, cobalt-, and copper-alloy brazing fillers. *Superbraz 250*, from Materials Resources International, is a *tin–silver–titanium brazing filler metal* that works at 480°F–540°F (250°C–280°C). Because of that low-temperature range, it can be considered more a solder than a braze. However, other ingredients activate conditions for surface wetting and joining, making it more a braze. In an aluminum–silicon–lithium brazing filler (aluminum alloy 4045 except for the lithium),

B

introduced by Kaiser Aluminum and Chemical Corp., the lithium (0.015%–0.1%, up to 0.3% if vacuum brazing) allows a fluoride flux to wet the surfaces to be joined before magnesium from the core alloy can “poison” the flux. An 82% *gold-18 indium brazing filler metal* having a solidus to liquidus temperatures of 843.8°F–905°F (451°C–485°C) was found by Sandia National Laboratory for brazing *Ferrallium 255 duplex stainless steel* and silver–nickel–silver laminates to copper. Gold alloy brazing foils containing 33%–35% nickel, 3%–4% chromium, 1%–2% iron, and 1%–2% molybdenum (*SK-1 gold brazing filler metal*) and 34%–36% nickel, 4%–4.5% chromium, and 2%–3% iron (*SK-2 gold brazing filler metal*), developed by GTE Laboratories, have a brazing temperature range of 1922°F–2102°F (1040°C–1150°C). They have been effective in brazing titanium-coated PY6 (6Y₂ O₃-modified *silicon nitride*) to *Incoloy 909* superalloy with a nickel interlayer at the *ceramic–metal* interface.

Brazing Procedure

The detailed methods and practices including all joint brazing procedures involved in the production of a brazement. See also *joint brazing procedure*.

Brazing Sheet

Brazing filler metal in sheet form.

Brazing Technique

The details of a brazing operation that, within the limitations of the prescribed brazing procedure, are controlled by the brazer or the brazing operator.

Brazing Temperature

The temperature to which the base metal is heated to enable the filler metal to wet the base metal and form a brazed joint.

Brazing Temperature Range

The temperature range within which brazing can be conducted.

Break

The process of parting into two or more pieces usually by some form of loading but excluding processes such as cutting. There are ill-defined subtleties in the choice between the terms “break,” “crack,” “cracking,” “fracture,” and “rupture.” This may reflect the fact that the first terms, with their Anglo-Saxon roots, or possibly seen as common usage, whereas the latter two with their Latin origins, may sound appropriately scientific to some ears or merely confusing jargon to others.

Break-In (Noun)

See *running in*.

Break On (Verb)

To operate a newly installed bearing, seal, or other tribocomponent in such a manner as to condition its surface(s) for improved functional operation. See also *run in* (verb).

Breakaway Oxidation

Oxidation in which the oxide repeatedly falls off. During the time that the oxide remains on the surface, the rate of oxidation falls progressively, but after a layer has spalled off, the rate immediately increases only to fall again as the oxide thickness builds again. As a result, over a long period, a continuing and fairly constant rate of attack is observed.

Breakaway Torque

See *starting torque*.

Breakdown

(1) An initial rolling or drawing operation applied to an ingot or a series of such operations, for the purpose of reducing a casting or extruded shape prior to the finish reduction to desired size. (2) A preliminary press forging operation.

Breakdown Potential

The least noble potential where *pitting* or *crevice corrosion*, or both, will initiate and propagate.

Breakdown Voltage

The voltage required, under specific conditions, to cause the failure of an insulating material. See also *dielectric strength* and *arc resistance*.

Breaker Plate

In plastic forming, a perforated plate located at the rear end of an extruder or at the nozzle end of an injector cylinder. It often supports the screens that prevent foreign particles from entering the die and is used to keep unplasticized material out of the nozzle and to improve distribution of color particles.

Breaking Extension

The elongation necessary to cause rupture of an adhesive and bonded test specimen. The tensile strain at the moment of rupture.

Breaking Factor

The breaking load divided by the original width of an adhesive and bonded test specimen, expressed in lb/in.

Breaking Load

The maximum load (or force) applied to a test specimen or structural member loaded to rupture.

Breaking Out

(1) Removal of a casting from its mold. (2) Fiber separation or break on surface plies at drilled or machined composite material edges.

Breaking Stress

Same as *fracture stress*.

Breaks

Creases or ridges usually in *untempered* or in aged material where the yield point has been exceeded. Depending on the origin of the breaks, they may be termed *cross breaks*, *coil breaks*, *edge breaks*, or *sticker breaks*.

Breather

A loosely woven material that serves as a continuous vacuum path over a part but is not in contact with the resin.

Breathing

The opening and closing of a mold to allow gas to escape early in the plastic molding cycle. Also called degassing; sometimes called bumping, in phenolic molding. When referring to plastic sheeting, the term breathing indicates permeability to air.

Breeze

Furnace ash of substantial form as opposed to the powder or fly ash. Such material can be bonded by cement to form building blocks.

Bremsstrahlung

See *continuum*.

Brick

Brick is a construction material usually made of clay and extruded or molded as a rectangular block. Three types of clay are used in the manufacture of bricks: surface clay, fire clay, and shale. Adobe brick is a sun-dried molded mix of clay, straw, and water, manufactured mainly in Mexico and some southern regions of the United States.

The first step in manufacture is crushing the clay. The clay is then ground, mixed with water, and shaped. Then the bricks are fired in a kiln at approximately 1093°C.

Substances in the clay such as Ferrous, magnesium, and calcium oxides impart color to the bricks during the firing process. The color may be uniform throughout the bricks, or the bricks may be manufactured with a coated face. The latter are classified as glazed, claycoat, or engobe. Engobes are ductile erosion behavior coatings, also called slurries, that are applied to plastic or dry body brick units to develop the desired color and texture. Claycoat is a type of engobe that is sprayed on as a coating of liquid clay and pigments.

Clay bricks are manufactured for various applications. The most commonly used brick product is known as facing brick. In addition to standard bricks, decorative bricks molded in special shapes are available in both standard and custom sizes. They are used to form certain architectural details such as water tables, arches, copings, and corners. Bricks are also used to create sculptures and murals.

Sand-lime bricks for fancy walls are of sand and lime pressed in an atmosphere of steam. They are not to be confused with the sand-lime bricks used for firebrick, which are of refractory silica sand with a lime band. Ceramic glazes and semiglazes are used on some building bricks especially on the yellow ones.

Bridge Die

In two-section extrusion die capable of producing tubing or intricate hollow shapes without the use of a separate mandrel.

Metal separates into two streams as it is extruded past a bridge section, which is attached to the main die section and holds a stub mandrel in the die opening; the metal then is rewelded by extrusion pressure before it enters the die opening. Compare with *porthole die*. See *extrusion*.

Bridging

(1) Premature solidification of metal across a mold section or ingot before the metal below or beyond solidifies. (2) Solidification of slag within a cupola at or just above the tuyeres. (3) Welding or mechanical locking of the charge in a down feed melting or smelting furnace. (4) In powder metallurgy, the formation of arched cavities in a powder mass. (5) In soldering, an unintended solder connection between two or more conductors, either securely or by mere contact. Also called a crossed joint or solder short.

Bright Annealing

Annealing in a protective medium to prevent discoloration of the bright surface.

Bright Bolt

See *bolt*.

Bright Dip

A solution that produces, through chemical action, a bright surface on an immersive metal.

Bright Finish

A high-quality finish produced on ground and polished rolls. Suitable for electroplating.

Bright Nitriding

Nitriding in a protective medium to prevent discoloration of the bright surface. Compare with *blank nitriding*.

Bright Plate

An electrodeposit that is lustrous in the as-plated condition.

Bright Range

The range of current densities, other conditions being constant, within which a given electroplating bath produces a bright plate.

Bright Stock

High-viscosity mineral oils that remain after vacuum distillation of crude oil.

Brightener

A material added to electroplating baths, etc., with the intention of producing a bright lustrous surface.

B

Bright-Field Illumination

For reflected light, the form of illumination that causes specularly reflected surfaces normal to the axis of the microscope to appear bright. For transmission electron microscopy, the illumination of an object so that it appears on a bright background. Compare with *dark-field illumination*.

Brillouin Zones

See *electron bands*.

Brine

Seawater containing a higher concentration of dissolved salt than that of the ordinary ocean.

Brine Quenching

A quench in which brine (saltwater chlorides, carbonates, and cyanides) is the quenching medium. The salt addition improves the efficiency of water at the vapor phase or hot stage of the quenching process.

Brinell Hardness Number (HB)

A number related to the applied load and to the surface area of the permanent impression made by a ball indenter computed from

$$HB = \frac{2P}{\pi D \sqrt{D - D^2 - d^2}}$$

where

P is the applied load, kgf

D is the diameter of the ball, mm

d is the mean diameter of the impression, mm

Brinell Hardness Test

A test for determining the hardness of a material by forcing a hard steel or tungsten carbide ball of specified diameter (typically, 10 mm) into it under a specified load. The resultant indentation diameter is then measured and, by comparison with established tables, a hardness is determined. The result is expressed as the *Brinell hardness number*. See *hardness*.

Brinelling

(1) Indentation of the surface of a solid body by repeated local impact or impacts, or static overload. Brinelling may occur especially in a rolling-element bearing. (2) Damage to a solid bearing surface *characterized* by one or more plastically formed indentations brought about by overload.

See also false Brinelling.

Briquette

A self-sustaining mass of powder of defined shape. See preferred term *compact* (noun).

Britannia Metal

An alloy of tin with, typically, about 7% antimony and 2% copper although there are variations. It is one of the range of pewters with mainly decorative applications.

British Association (Threads)

A series of thread sizes of standard profile used mainly in electrical and electronic applications rather than mechanical engineering.

British Thermal Unit

The quantity of heat required to raise the temperature of 1 lb of water by 1°F.

Brittle

(1) Permitting little or no plastic (permanent) deformation prior to fracture. (2) Failing without significant ductility. Sometimes, the term is used to imply susceptibility to failure under impact loading but materials can fail in a brittle manner even under static loads.

Brittle Crack Propagation

A very sudden propagation of a crack with the absorption of no energy except that stored elastically in the body. Microscopic examination may reveal some deformation even though it is not noticeable to the unaided eye. Contrast with *ductile crack propagation*.

Brittle Edge Technique

A technique for impact and bend test specimens to prevent the initiation of shear lips.

Brittle Erosion Behavior

Erosion behavior having characteristics (e.g., little or no plastic flow, the formation of cracks) that can be associated with *brittle fracture* of the exposed surface. The maximum removal occurs at an angle near 90°, in contrast approximately 25° for *ductile erosion behavior*.

Brittle Fracture

(1) Generally, cracking without associated ductility and, usually, with only a small energy input. In a narrower sense, the term is associated with the change from ductile to brittle behavior that some metals, particularly iron and other metals with a body-centered cubic structure, undergo as the temperature falls. In the case of many steels, this occurs at about ambient temperature. Above the brittle to ductile transition, this steel will accept deformation, that is, absorb energy and act in a ductile manner, before failing by overloading. Such behavior makes the metal tolerant of minor cracks and other stress-raising features, reduces sensitivity to impact and may give warning of imminent failure. Below the transition, the steel will be sensitive to cracks and impact loads and may fail without warning even under apparently static loads. Above the transition the fracture mode is shear, that is, planes of atoms sliding over each other, while at lower temperatures, the mode changes to cleavage in which the planes peel apart. Although the fractures are both transgranular, the surface produced by the two modes is quite distinct, one being a dull grey and the cleavage bright and crystalline, so the change from one to the other is readily observed on a series of test pieces broken over a range of temperatures. The % crystallinity of the test pieces broken at the various temperatures is noted to determine the fracture appearance transition temperatures (FATT), that is, the temperature at which the fracture is 50% ductile and 50% cleavage. The test pieces are often broken in an impact test and the energy required

to break the specimens is then plotted against the temperature. The large step change in toughness, as measured by the energy absorbed, takes place over a limited range, typically of about 50°C, but above and below this range, any change is gradual. Consequently, the terms upper shelf and lower shelf are used with reference to the respective parts of the curve and for behavior that is, respectively, fully ductile or fully brittle. Brittle fracture has been responsible for many major and dramatic failures of ships, bridges, pressure vessels and pipelines, etc. (2) Separation of a solid accompanied by little or no macroscopic plastic deformation. Typically, brittle fracture occurs by rapid crack propagation with less expenditure of energy than that for *ductile fracture*. Brittle tensile fractures have a bright, granular appearance and exhibit little or no necking. A *chevron pattern* may be present on the fracture surface, pointing toward the origin of the crack, especially in brittle fractures in flat platelike components. Examples of brittle fracture include *transgranular cracking* (*cleavage and quasi-cleavage fracture*) and *intergranular cracking* (*decohesive rupture*).

Brittleness

(1) A lack of ductility, sensitivity to cracks, and low absorption of energy during crack propagation. See *brittle fracture*. (2) The tendency of a material to fracture without first undergoing significant *plastic deformation*. Contrast with *ductility*.

Broaching

Cutting with a tool that consists of a bar having a single edge or a series of cutting edges (i.e., teeth) on its surface. The cutting edges of a multiple-tooth, or successive single-tooth, bridges increase in size and/or change in shape. The broach courage of a straight line or axial direction when relative motion is produced in relation to the workpiece, which may also be rotating. The entire cut is made in single or multiple passes over the workpiece to shape the required surface contour.

Broad Goods

Fiber woven to form fabric up to 1270 mm (50 in.) wide for reinforcement of plastics. It may or may not be impregnated with resin and is usually furnished in coils of 25–140 kg (50–300 lb).

Bromine

An elementary material, symbol Br. It is a reddish-brown liquid having a boiling point at 138°F (59°C). It gives off very irritating fumes and is highly corrosive. It is one of four elements called *halogens*, and its name is derived from Greek words meaning *salt producer*. They are fluorine, chlorine, iodine, and bromine. They are all chemically active, combining with hydrogen and most metals to form *halides*. Bromine is less active than chlorine but more so than iodine. It is moderately soluble in water. It never occurs free in nature, and it is obtained from natural bromide brines by oxidation and steaming or by electrolysis. It occurs in seawater to the extent of 65–70 parts per million and is extracted. It is marketed 99.7% minimum purity with specific gravity not less than 3.1, but dry elemental bromine, Br₂, is marketed 99.8% pure for use as a brominating and oxidizing agent. For these uses, also, bromine is available as a crystalline powder as *dibromodimethylhydantoin*, containing 55% bromine. *Brom 55* is this material. Bromine is also used as a flame retardant in plastics, although its use as such has been questioned due to environmental concerns.

It is used in the manufacture of agricultural chemicals, dyes, photographic chemicals, poison gases for chemical warfare, pharmaceuticals, disinfectants, and many chemicals. It is also employed in the extraction of gold. Bromine's major end use, as ethylene dibromide for scavenging lead antiknock compounds in gasoline, is decreasing as these environmentally hazardous additives are phased out.

Bronze

The term “bronze” is generally applied to any copper alloy that has as the principal alloying element a metal other than zinc or nickel. Originally the term was used to identify copper–tin alloys that had tin as the only, or principal, alloying element. Some brasses are called bronzes because of their color, or because they contain some tin. Most commercial copper–tin bronzes are now modified with zinc, lead, or other elements.

The *copper–tin bronzes* are a rather complicated alloy system. The alloy with up to about 10% tin has a single-phase structure. Above this percentage, a second phase, which is extremely brittle, can occur, making plastic deformation impossible. Thus high-tin bronzes are used only in cast form. Tin oxide also forms in the grain boundaries, causing decreased ductility, hot workability, and castability. Additions of small amounts of phosphorus, in the production of phosphor bronzes, eliminate the oxide and add strength. Because tin additions increase strength to a greater extent than zinc, the bronzes as a group have higher strength than brasses—from around 414 to 724 MPa in the cold-worked high-tin alloys. In addition, fatigue strength is high.

Bronzes containing more than 90% copper are reddish; below 90% the color changes to orange-yellow, which is a typical bronze color. Ductility rapidly decreases with increasing tin content. Above 20% tin, the alloy rapidly becomes white and loses the characteristics of bronze. A 90% copper and 10% tin bronze has a density of 0.317 lb/in.³ (8775 kg/m³); an 80%–20% bronze has a density of 0.315 lb/in.³ (8719 g/m³). The 80%–20% bronze melts at 1868°F (1020°C), and 95%–5% bronze melts at 2480°F (1360°C).

The family of *aluminum bronzes* is made up of alpha-aluminum bronzes (less than about 8% aluminum) and alpha-beta bronzes (8%–20% aluminum) plus other elements such as iron, silica, nickel, and manganese. Because of the considerable strengthening effect of aluminum, and the hard condition these bronzes are among the highest-strength copper alloys. Tensile strength approaches 690 MPa. Such strengths plus outstanding corrosion resistance make them excellent structural materials. They are also used in wear-resistance applications and for nonsparking tools. Phosphor bronzes have a tin content of 1.25%–10%. They have excellent mechanical and cold-working properties and a low coefficient of friction, making them suitable for springs, diaphragms, bearing plates, and fasteners. Their corrosion resistance is also excellent. In some environments, such as salt water, they are superior to copper. *Leaded phosphor bronzes* provide improved machinability. *Silicon bronzes* are similar to aluminum bronzes. Silicate content is usually between 1% and 4%. In some, zinc and manganese are also present. Besides raising strength, the presence of silicon sharply increases electrical resistivity. Aluminum–silicon bronze has exceptional strength and corrosion resistance and is particularly suited to hot working.

Gear bronze may be any bronze used for casting gears and worm wheels, but usually means a tin bronze of good strength deoxidized with phosphorus and containing some lead, to make it easy to machine and to lower the coefficient of friction. A typical gear bronze contains 88.5% copper, 11% tin, 0.25% lead, and 0.25% phosphorus. It has a tensile strength of up to 276 MPa, elongation 10%,

B

and Brinell hardness of 70%–80%, or up to 90% when chill-cast. The density is 0.306 lb/in.³ (8470 kg/m³). This is *SAE bronze No. 65*. A *hard gear bronze*, or *hard bearing bronze*, contains 84%–86% copper, 13%–15% tin, up to 1.5% zinc, up to 0.75% nickel, and up to 0.5% phosphorus. Hard and strong bronzes for gears are often silicon bronze or manganese bronze.

In a modified 90–10 type of bronze, the zinc is usually from 2% to 4% and the lead up to 1%. A cast bronze of this type will have a tensile strength of about 276 MPa, elongation of 15%–25%, and a Brinell hardness of 60%–80%, those high in zinc being the stronger and more ductile and those high in lead being the weaker. Bronzes of this type are much used for general castings and are classified as *composition metal* in the United States. In England, they are called *engineer's bronze*.

Architectural bronze, or *art bronze*, is formulated for color and is very high in copper. One foundry formula for art bronze of a dull red color calls for 97% copper, 2% tin, and 1% zinc. For ease of casting, however, they are more likely to contain lead, and a *gold bronze* for architectural castings contains 89.5% copper, 2% tin, 5.5% zinc, and 3% lead. In leaded bronze, the hard copper–tin crystals aid in holding the lead in solution. These bronzes are resistant to acids and are grouped as a valve bronze, or as bearing bronze because of the hard crystals in a soft matrix. Federal specifications for bronze give 10 grades in wide variations of tin, zinc, and lead. The ASTM designates five grades of *bronze casting alloys*. *Alloy No. 1* contains 85% copper, 10% tin, and 5% lead; *alloy No. 5* contains 70% copper, 5% tin, and 25% lead. The British *coinage copper* is a bronze containing 95.5% copper, 3% tin, and 1.5% zinc.

Many of these bronzes are designated by alloy number and grouped into several families of standard alloys. There are four principal families of wrought bronze: *copper-tin-phosphorus alloys*, or *phosphor bronzes* (C 50100 to C 52400); *copper-tin-phosphorus-lead alloys*, or *leaded phosphor bronzes* (C53200 to C54800); *copper-aluminum alloys*, or *aluminum bronzes* (C60600 to C64400); and *copper-silicon alloys*, or *silicon bronzes* (C64700 to C66100). A few, such as two *manganese bronzes*, are included in the copper-zinc family of copper alloys. The aluminum bronze family is the largest, containing nearly three dozen standard compositions.

Casting alloys comprise five main families: *copper-zinc-manganese alloys*, or *manganese bronzes* (C86100 to C 86800); *copper-tin alloys*, or *tin bronzes* (C90200 to C91700); *copper-tin-lead alloys*, or *leaded and highly leaded tin bronzes* (C92200 to C94500); *copper-tin-nickel alloys*, or *nickel-tin bronzes* (C94700 to C 94900); and *copper-aluminum alloys*, or *aluminum bronzes* (C95200 to C 95900). *Copper-silicon bronzes* are included in the C87300 to C87900 family of copper-silicon alloys.

Flat products—0.12 in (3 mm) thick *aluminum bronze C61400*—have tensile yield strengths ranging from 310 MPa in the annealed (O60) temper to 414 MPa after cold working to the H04, or hard, temper, with ductility decreasing from 40% to 32% elongation, respectively. All casting alloys can be sand-cast, many can be centrifugally cast, and some can be permanent mold, plaster-, and investment-cast but not die-cast. Among the strongest is *manganese bronze C86300*, which, as cast in sand molds, provides a minimum tensile yield strength of 414 MPa and at least 12% elongation. Some bronzes, such as *nickel-bearing silicon bronzes* and aluminum bronzes, especially those containing more than 9% aluminum, can be strengthened by age-hardening.

Unfortunately, the term “bronze” has occasionally been coupled with a trade or brand name for some alloys having properties inferior to what might be inferred from the name. See also *gunmetal*, *phosphor bronze*, and *cold cast bronze*.

Bronze Powder

Pulverized or powdered bronze made in flake form by stamping from sheet metal. It is used chiefly as a paint pigment and as a dusting powder for printing. In making the powder, the sheets are worked into a thin foil, which becomes harder under the working and breaks into small flakes. Lubricant keeps flakes from sticking to one another. Usually stearic acid is used, but in the dusting powder, hot water or nonsticky lacquers are used. The powder is graded in standard screens and is then polished in revolving drums with a lubricant. This gives it the property of leafing or forming a metallic film in the paint vehicle. The leaf is also called *composition leaf*, or *Dutch metal leaf*, when used as a substitute for gold leaf. Flitters are made by reducing thin sheets to flakes, and they are not as fine as bronze powder. *Alpha bronze*, a prealloyed 91% copper, 10% tin powder from Makin Metal Powders of England for powder-metal parts, provides greater green strength and less wear and noise in bearing applications than a premixed 90–10 composition.

The compositions of bronze powder vary, and seven alloys form the chief commercial color grades from the reddest, called *pale gold*, which is 95% copper and 5% zinc, to the rich gold which has 70% copper and 30% zinc. Colors are also produced by heating to give oxides of deep red, crimson, or green-blue. The powder may also be dyed in colors, using tannic acid as a mordant, or treated with acetic acid or copper acetate to produce an antique finish. The color or tone of bronze powders may also be adjusted in paints by adding a proportion of mica powder. A *white bronze powder* is made from aluminum bronze, and the silvery colors are obtained with aluminum powder. The bronze powder of 400 mesh used for inks is designated as extra fine. The fine grade, for stencil work, is 325 mesh. Medium fine, for coated paper, has 85% of the particles passing through a 325-mesh screen and 15% retained on the screen. A 400-mesh powder has 500 million particles per gram. The old name for bronze powder is *gilding powder*. It is also called *gold powder* when used in cheap gold-colored paints, but bronze powders cannot replace gold for use in atmospheres containing sulfur, or for printing on leather where tannic acid would corrode the metal. *Gold pigments* used in plastics are bronze powders with oxygen stabilizers.

Bronze Welding

A process for Makin fusion joints with brazing filler metals, particularly using arc welding techniques, but forming large bulky deposits rather than the thin capillary film characteristic of true brazing. See *brazing*.

Bronzing

(1) Applying a chemical finish to copper or copper-alloy surfaces to alternate color. (2) Plating a copper-tin alloy on various materials.

Brush Anodizing

An anodizing process similar to *brush plating*.

Brush Plating

Plating with a concentrated solution or gel held in or fed to an absorbing medium, pad, or brush carrying the anode (usually insoluble). The brush is moved back and forth over the area of the cathode to be plated.

Brush Polishing (Electrolytic)

A method of electropolishing in which the electrolyte is applied with a pad or brush in contact with the part to be polished.

B-Stage

An intermediate stage in the reaction of certain thermosetting resins in which the material softens when heated and swells when in contact with certain liquids, but may not entirely fuse or dissolve. The resin is an uncured thermosetting adhesive, usually in the stage. Synonym for resitol. Compare with *A-stage* and *C-stage*.

B-Stage Resin

In a thermosetting reaction, a resin that is in an intermediate state of cure when it is sticky, or tacky, and capable of further flow. The cure is normally complete during the laminating cycle. See *C-stage resin* and *prepreg*.

Bubble

A spherical, internal void, or globule of air or other gas trapped within a plastic. See *void*.

Bubbler

In forming of plastics, a device inserted into a mold force, cavity, or core, which allows water to flow deep inside the hole into which it is inserted and to discharge through the open end of the hole. Uniform cooling of the mold and of isolated mold sections can be achieved in this manner.

Bubbler Mold Cooling

In injection molding of plastics, a method of uniformly cooling a mold; a stream of cooling liquid flows continuously into a cooling cavity equipped with a coolant outlet normally positioned at the opposite end.

Bubbly Oil

Oil containing bubbles of gas.

Buckle

(1) Bulging of a large, flat face of a casting; in investment casting, cause my *dip coat* peeling from the pattern. (2) An indentation in a casting, resulting from expansion of the sand, can be termed the start of an expansion defect. (3) A local waviness in metal bar or sheet, usually transverse to the direction of rolling.

Buckling

(1) A mode of failure generally characterized by an unstable lateral material deflection due to compressive action on the structural element involved. (2) In metal forming, a bulge, bend, kink, or other wavy condition of the workpiece caused by compressive stresses. See also *compressive stress*.

Buckyballs

Buckyballs, the soccer-shaped molecules discovered over a decade ago, are made entirely of carbon atoms linked with unusual chemical bonds.

Buckyballs have a spherical structure with their surfaces made up of from 28 to 450 carbon atoms and hexagonal and pentagonal arrays, with 60 carbon atoms being the most stable. This soccerball shaped configuration is reminiscent of R. Buckminster Fullers geodesic domes, hence the name Buckminster Fullerene or "buckyball."

Buckybowls, large fragments of buckyballs, have been synthesized. The molecules have the ability to take up electrons and give them back later, under the right conditions, and higher concentration than buckyballs.

The only practical application thus far has been the computer industry's use of another relative, the bulkytube, as in atomic-scale probe. Some researchers believe that the buckybowls may facilitate the development of plastic batteries that would be lighter, smaller, and more environmentally friendly than the rechargeable batteries now used in our cellular phones and laptop computers.

The shape of the molecule may also allow it to bond with other molecules. It fits over the buckyball much like a contact lens and may be able to serve as a medium that links other substances to the balls.

Bucky Diaphragm

An x-ray scanner reducing device originally intended for medical radiography but also applicable to industrial radiography in some circumstances. Thin strips of lead, with their widths held parallel to the primary radiation, are used to absorb scattered radiation preferentially; the array of strips is in motion during exposure to prevent formation of a pattern on the film.

Buffer

(1) A substance which by its addition or presence tends to minimize the physical and chemical effects of one or more of the substances in a mixture. Properties often buffered include pH, oxidation potential and flame or Pfizer temperatures. (2) A substance whose purpose is to maintain a constant hydrogen-ion concentration in water solutions, even where acids or alkalis are added. Each buffer has a characteristic limited range of pH over which it is affected.

Buffer Gas

A protective gas curtain at the charge or discharge end of a continuously operating sintering furnace.

Buffing

Polishing of a surface usually by a high-speed rotating soft fabric wheel, the Bob, carrying some polishing compound. The term may imply a process of surface mirroring rather than a clean cutting action.

Buffing Wheel

Buff sections assembled to the required face with for use on a rotating shaft between flanges. Sometimes called a buff.

B

Buff Section

A number of fabric, paper, or leather disks with concentric center holes held together by various types of sewing to provide degrees of flexibility or hardness. These sections are assembled to make wheels for polishing.

Builder

A material, such as an alkali, a buffer, or a water softener, added to a soap or synthetic surface-active agent to produce a mixture having enhanced detergency. Examples: (1) alkalis—caustic soda, soda ash, and trisodium phosphate. (2) *buffers*—sodium metasilicate and borax; and (3) water softeners—sodium tripolyphosphate, sodium tetraphosphate, sodium hexametaphosphate, and ethylene diamine tetraacetic acid.

Building Stone

Any stone used for building construction may be classified as building stone. *Granite and limestone* are among the most ancient of building materials and are extremely durable. Two million limestone and granite blocks, totaling nearly 8,000,000 long tons (8128 million kg), were used in the peer amid of Giza, built about 2980 B.C., the granite being used for casing. Availability, or a near supply, may determine the stone used in ordinary building, but for public buildings stone is transported long distances. Some sandstones, such as the *red sandstone* of the Connecticut Valley, weather badly and are likely to scale off with penetration of moisture and frost. Granite will take heavy pressures and is used for foundation tiers and columns. Limestones and well-segmented sandstones are employed extensively above the foundations. Nearly half of all the lifestyle used in United States and block form is Indiana limestone. Marble has a low crushing strength and is usually an architectural or facing stone.

Crushed stone is used for making concrete, for railway ballast, and for road making. The commercial stone is quarried, crushed, and graded. Much of the crushed stone used is granite, limestone, and *trap rock*. The last is a term used to designate basalt, gabbro, diorite, and other dark-colored, fine-grained igneous rocks. Graded crushed usually consists of only one kind of rock and is broken with sharp edges. *Granite granules* for making hard terazzo floors are marketed in several sizes, and in pink, green, and other selected colors. *Roofing granules* are grated particles of crushed rock, slate, slag, porcelain, or tile used as surfacing on asphalt roofing and shingles. Granules have practically superseded gravel for this purpose. *Ceramic granules* are produced from clay or shale, fired and glazed with metallic salts. They are preferred because the color is uniform.

Building Up

To electroplate, metal spray, etc., to increase or restore dimensions. Compare with *surfacing*. Also the same as *buildup*.

Buildup

(1) Excessive electrodeposition that occurs on high current-density areas, such as corners or edges. (2) In welding, the sequence of deposition of multiple layers or beads to form a bulk weld.

Buildup Sequence

(1) The order in which the weld beads of a multi-pass weld are deposited with respect to the cross section of the joint. See also *block sequence* and *longitudinal sequence*.

Built-Up Edge

(1) Chip material adhering to the tool face adjacent to the cutting edge during cutting. (2) Material from the workpiece, especially a machining, which is stationary with respect to the tool. See also *wedge formation*.

Built Up Laminated Wood

An assembly made by joining layers of lumber with mechanical fastenings so that the grain of all laminations is essentially parallel.

Bulb Section

Rolled or extruded bar having one edge much thicker than the other, the transition being fairly abrupt rather than a continuous taper.

Bulging

(1) Expanding the walls of a cup, shell, or tube within an internally expanded segmented punch or a punch composed of air, liquids, or semiliquids such as waxes, rubber, and other elastomers. (2) The process of increasing the diameter of a cylindrical shell (usually to a spherical shape) or of expanding the outer walls of any shell or box shape whose walls were previously straight.

Bulk Adherend

With respect to interphase, the adherend, unaltered by the adhesive. Compare with *bulk adhesive*.

Bulk Adhesive

With respect to interphase, the adhesive, unaltered by the adherend. Compare with *bulk adherend*.

Bulk Density

(1) The weight of an object or material divided by its material volume less the volume of its open pores. (2) The density of a plastic molding material in loose form (granular, nodular, and so forth), expressed as a ratio of weight to volume. (3) Metal powder in a container or bin expressed in mass per volume.

Bulk Factor

The ratio of the volume of a raw plastic molding compound or powdered plastic to the volume of the finished, solid piece produced from it. The ratio of the density of the solid plastic object to the apparent, or bulk, density of the loose molding powder.

Bulk Forming

Forming processes, such as extrusion, forging, rolling, and drawing, in which the input material is in billet, ride, or slab form and a considerable increase in surface-to-volume ratio in the formed part

occurs under the action of largely compressive loading. Compare with *sheet forming*.

Bulk Modulus of Elasticity (*K*)

The measure of resistance to change in volume; the ratio of hydrostatic stress to the corresponding unit change in volume. This elastic constant can be expressed by:

$$K = \frac{\sigma_m}{\Delta} = \frac{-p}{\Delta} = \frac{1}{\beta} = -$$

where *K* is the bulk modulus of elasticity, σ_m is hydrostatic or mean stress tensor, *p* is hydrostatic pressure, and β is compressibility. Also known as bulk modulus, compression modulus, hydrostatic modulus, and volumetric modulus of elasticity.

Bulk Molding Compound

BMC is a puttylike mixture of thermosetting polyester, vinyl ester or phenolic resins, additives, fillers, pigments, and/or reinforcements generally extruded into shapes for compression, transfer, or injection molding. Bulk Molding Compounds Inc. makes a dozen product series compounds, including general-purpose, electrical, medium- and high-strength, food-contact, and corrosion-resistant types. Applications include electrical coil bobbins, brush holders and connectors, dishwares, pants, trays, tubs, and housings for headlamp reflectors, small appliances, auto parts, and hand-held power tools. **Nu-Stone**, of Industrial Dielectrics, is a BMC that looks like granite.

Bulk Sample

See *gross sample*.

Bulk Sampling

Obtaining a portion of a material that is representative of the entire lot.

Bulk Volume

The volume of the metal powder fill in the die cavity.

Bull Block

A machine with a power-driven revolving drum for cold drawing wire through a drawing die as the wire winds around the drum.

Bulldozer

Slow-acting horizontal *mechanical press* with a large bed used for bending and straightening. The work is done between dies and can be performed hot or cold. The machine is closely allied to a forging machine.

Bullion

(1) A semirefined alloy containing sufficient precious metal to make recovery profitable. (2) Refined gold or silver, uncoined. (3) In bulk, that is, as ingots or bar rather than a finished product.

Bulls-Eye Structure

The microstructure of malleable or ductile cast iron when graphite nodules are surrounded by a ferrite layer in a pearlitic matrix.

Bump Check

See *percussion cone*.

Bumper

A machine used for packing molding sand in a flask by repeated jarring or jolting. See also *jolt ramming*.

Bumping

(1) Forming a dish in metal by means of many repeated blows. (2) Forming a head. (3) Setting the seams on sheet metal parts. (4) Ramming sand in a flask by repeated jarring and jolting.

Bundle

A general term for a collection of essentially parallel filaments or fibers using composite materials.

Burden

(1) The total material charge into a furnace or other reaction vessel. (2) In submerged arc welding, the total amount of fused and unfused flux over the weld metal.

Buret

An instrument used to deliver variable and accurately known volumes of a liquid during titration or volumetric analysis. Burets are usually made from uniform-bore glass tubing in capacities of 5 to 100 mL, the most common being 50 mL. See also *titration* and *volumetric analysis*.

Burgers Vector

The total lattice translation resulting from the passage of a dislocation. See *dislocation*.

Burlap

A coarse, heavy cloth made of plane-woven jute, or jutelike fibers, and used for wrapping and bagging bulky articles, for upholstery linings, and as a backing fabric for linoleum. Finer grades are used for wall coverings. The standard burlap from India is largely from jute fibers, but some hibiscus fibers are used. For bags and wrappings, the weave is coarse and irregular, and the color is the natural tan. The coarse grades such as those used for wrapping cotton bales are sometimes called *gunny* in the United States, but *gunny* is a general name for all burlap in Great Britain. Dundee, Scotland, is the important center of burlap manufacture outside of India, but considerable quantities are made from native fibers in Brazil and other countries. Burlap is woven in widths up to 144 in (3.6 m), but 36, 40, and 50 in (0.91, 1.02, and 1.27 m) are the usual widths. Hessian is the name of a 9.5 oz (269 g), plane-woven finer burlap made to replace an older fabric of the same name woven from coarse and heavy flax fibers. When dyed in colors, it is used for linings, wall coverings,

B

and upholstery. *Brattice cloth* is a very coarse, heavy, and tightly woven jute cloth, usually 20 oz (567 g) used for gas breaks in coal mines; but a heavy cotton duck substituted for the same purpose is called by the same name. Most burlap for commercial bags is 8, 9, 10, and 12 oz (226, 255, 283, at 340 g), feed bags being 8 oz (226 g), and grain bags 10 oz (283 g).

Burn

(1) The heat treatment to which refractory materials are subjected in the firing process. (2) To heat particulate material, grain, aggregate, refractory bricks, or ceramic ware in a furnace or kiln, sufficient to cause desired chemical, structural, or crystalline changes in the material though below the melting point of the major component. To fire, to calcine, or sinter; usually more intense than to dry or to activate.

Burn Off Rate

The rate at which a welding electrode or other consumable item is melted or otherwise consumed.

Burn Through (of Weld)

A hole completely through a welded joint due to local collapse of the weld pool.

Burnback Time

See preferred term *meltdown time*.

Burned

Showing evidence of thermal decomposition or charring through some discoloration, distortion, destruction, or conversion of the surface of the plastic, sometimes to a carbonaceous char.

Burned Deposit

A dull, nodular electrodeposit resulting from excessive plating current density.

Burned-In Sand

A defect consisting of a mixture of sand and metal coherent to the surface of a casting.

Burned-On Sand

A mixture of sand and cast metal adhering to the surface of a casting. In some instances, may resemble *metal penetration*.

Burned Plating

See *burned deposit*.

Burned Sand

Foundry sand in which the binder or bond has been removed or impaired by contact with molten metal.

Burner

See preferred term *oxygen cutter*.

Burning

(1) Permanently damaging a metal or alloy by heating to cause either incipient melting or intergranular oxidation. See also *overheating* and *grain boundary liquitation*. The various forms of damage include severe grain growth, surface cracking, and grain boundary liquation. Decarburization, gross oxidation, and penetration of oxide intrusions down grain boundaries. (2) During subcritical annealing, particularly in continuous annealing, production of a severely decarburized and grain-coarsened surface layer that results from excessively prolonged heating to an excessively high temperature. (3) In grinding, getting the work hot enough to cause discoloration or to change the microstructure by tempering or hardening. (4) In sliding contacts, the oxidation of a surface due to local eating in an oxidizing environment. See also *metallurgical burn*. (5) An alternative term for flow welding techniques where bulk molten metal is poured into a substantial gap between the two phases to be joined. Sufficient heat input to melt the joint faces is insured by the molten metal being superheated or being allowed to flow to waste across the joint. Lead burning usually refers to the joining of lead components, by autogenous welding, that is, without the addition of solder or any other filler. (6) The term is also colloquially used for flow weld techniques for localized repair in which new material is cast into place in a temporary mold formed around the damaged area of the component. In practice molten metal is usually allowed to flow through the mold to waste until the parent metal edges have use. It is essentially the same as burning (5) but "burning on" is particularly associated with marine repairs such as two propellers.

Burning (Firing) of Refractories

The final heat treatment in a kiln to which refractory brick and shapes are subjected in the process of manufacture for the purpose of developing bond and other necessary physical and chemical properties.

Burning In

See preferred term *flow welding*.

Burning Rate

The tendency of plastic articles to burn at given temperatures.

Burning (Welding)

See preferred term *oxygen cutting*.

Burnish

(1) To alter the original manufactured surface of a sliding or rolling surface to a more polished condition. (2) To apply a substance to a surface by rubbing.

Burnishing

Finished sizing and smooth finishing of surfaces (previously machined or ground) by displacement, rather than removal, of minute surface irregularities with smooth-point or line-contact fixed or rotating tools.

Burnoff

(1) Unintentional removal of an autocatalytic deposit from a non-conducting substrate, during subsequent electroplating operations, owing to the application of excessive current or a poor contact area. (2) Removal of volatile lubricants such as metallic stearates from metal powder compacts by heating immediately prior to sintering.

Burnoff Rate

See preferred term *melting rate*.

Burnout

In casting, firing a mold and a high temperature to remove pattern material residue.

Burn-Through

A term erroneously used to denote excessive melt-through or a hole. See also *melt-through*.

Burn-Through Weld

A term erroneously used to denote AC weld or spot weld.

Burnt

See *burning*.

Burnt Deposit

In electroplating, the nodules and scabs formed by faulty conditions such as excess current density. See also *burning*.

Burnt Weld

A weld that has suffered significant oxidation particularly penetration and grain boundaries. It usually results from heating for excessive periods or an excessive temperatures, particularly in the presence of higher than normal levels of oxygen.

Burr

(1) A thin ridge or roughness (turned over edge) left on a workpiece (e.g., forgings or sheet metal blanks) resulting from cutting, punching, or grinding. (2) A rotary tool having teeth similar to those on hand files.

Burring

Same as *deburring*.

Burst Strength

A measure of the ability of the material to withstand internal hydrostatic or gas dynamic pressure without rupture. Hydraulic pressure required to burst a vessel of given thickness.

Bus (Bar)

A metal conductor for electricity. Usually a high current carrying capacity and no insulation are applied.

Bush Bearing

A plain bearing in which the lining is closely fitted into the housing in the form of a bush, usually surfaced with a bearing alloy.

Bushing

A bearing or guide, for a shaft etc. usually carried in a housing.

Butadiene

Also called *divinyl*, *vital ethylene*, *erythrene*, and *pyrrolylene*.

A colorless gas used in the production of neoprene, nylon, latex paints, and residents. Butadiene has a boiling point of 26.6 °F (−3 °C) and a specific gravity of 0.6272. Commercial butadiene is at least 98% pure.

Butadiene is also obtained as an ethylene coproduct during the steam cracking of naphtha or gas oil. It is also made by oxidation the hydrogenation of *n*-butenes, the dehydrogenation of butanes, and conversion of ethyl alcohol. The largest use for butadiene is the production of elastomers, such as *polybutadiene*, *styrene-butadiene*, *poly chloroprene*, and *acrylonitrile-butadiene*, or *nitrile rubbers*.

Butadiene is insoluble in water but soluble in alcohol and ether, obtained from the cracking of petroleum, from coal tar been seeing, or from acetylene produced from coke and lime. It is widely used in the formation of copolymers with styrene, acrylonitrile, vinyl chloride, and other monomeric substances and imparts flexibility to the result moldings.

Butadiene-Styrene Thermosetting Resins

Butadiene-styrene resins are low-molecular-weight, all-hydrocarbon, thermosetting copolymers designed primarily for surface coatings. They form tough, inert films by numerous and different mechanisms: oxidation, polymerization, solvent evaporation, and through the use of cross-linking agents.

Proper selection of curing conditions and/or modifiers provides conversions ranging from seconds to hours at temperatures from 21.1 °C to 593 °C.

Butadiene-styrene resins are prepared in a variety of forms. The basic resin is a viscous, clear material with a high degree of on saturation. It is supplied in a solvent-free state for use in special applications such as camel linings and thin-film metal-strip coatings. It is readily soluble in hydrocarbons thinners and chlorinated hydrocarbons. Another resin is based on butadiene alone. It is similar in molecular weight of physical properties to the basic resin; however, it possesses certain metal wedding and fabrication characteristics that make it superior for such uses as template coatings. Other resins are produced by modifying the base resin to introduce such polar groups as hydroxyls, carbonyls, and carboxyls. As a result, they have a much more active chemical nature and are more compatible with other coding resins then either the previous two.

A wide range of film properties can be obtained by varying cure conditions or by modification with other resins and cross-linking agents. Basically, films have excellent hardness and flexibility as well as abrasion resistance equal or superior to other high-quality industrial coating resins.

B

Adhesion: Films provide excellent adhesion to steel, galvanized tinplate, aluminum, brass, and die cast zinc. A wide variety of plastics, wood, glass, untreated concrete, and most other surfaces can also be coated successfully.

Chemical resistance: Butadiene-styrene films have excellent resistance to corrosive atmospheres, particularly salt-spray and detergents solutions. And chemical resistance, the films are generally equivalent or superior to other chemically resistant coating systems. Typical properties of baked butadiene-styrene films include extended resistance to water, salt water, acids, and ketones, alcohols, aromatics, and other solvents.

Some butadiene-styrene resins are frequently combined with other resins to obtain specific coating properties. They are used as modifiers for such leading conventional coding resins as alkyd, vinyl, acrylic, and epoxy. They can also be modified with other resins, primarily ureas, melamine, and nitrocellulose.

Butadiene-styrene resins can be cured by several systems—air-dry, low-temperature bake, high-temperature bake, and instant curing (2 s at 427 °C).

For means of instant cure have been found suitable: flame curing, high-density infrared heating, flame spraying, and induction heating. The principle is simply to supply a great deal of heat to the coating as rapidly as possible.

With the addition of metallic driers, butadiene-styrene resins will air-dry in 8 to 24 h. Curing time is rapid, however, when the resin is modified with nitrocellulose. This rapid lacquer-type drying composition is particularly suitable for wood furniture and hardboard finishes.

The resin is best suited for use in special thin-film coatings are up to 1.2 mils in thickness and are used in applications such as camel linings, flat steel primers, beverage-can base coats, as well as sanitary enamels. Additionally, automobile appliances, metal wall partitions, and preprimed steel sheeting are among the other uses for the resins in the primer field.

In the lacquer field, a resin modified with nitrocellulose produces non-penetrating, high-build, high-solids, chemically resistant finishes for such uses as wood furniture, metal cabinets, and plastics. This resin system is also suitable as the primer-surfacer for hardboard and wall paneling.

Other uses of butadiene-styrene resins include metal strip coatings and pipe coatings produced by instant cure methods and coatings for drum and tank liners.

Butler Finish

A semilustrous metal finish composed of fine, uniformly distributed parallel lines, usually produced with a soft abrasive buffing wheel; similar in appearance to the traditional hand-rubbed finish on silver.

Butter Coat

A commonly used term to describe a higher than usual amount of surface resin. See also *resin-rich area*.

Butterfly Extrusion

A technique for produce and deeply recessed sections by extruding a section with an open, flatter profile and then folding the product to produce the deep profile.

Buttering

A form of surfacing in which one or more layers of weld metal are deposited on the growth phase of one member (for example, a

high-alloy will deposit on steel base metal that is to be welded to a dissimilar base metal). The buttering provides a suitable transition will deposit for subsequent completion of the butt weld (joint). The composition of the blood or usually differs from those of the main weld and the parent metal. The technique is used, for example, where there is a need for a progressive transition between differing parent materials or where some characteristic of the main weld metal is incompatible with the parent.

Butt Fusion

A method of joining pipe, sheet, or other similar forms of a thermoplastic resin in which the ends of the two pieces to be joined are needed to the molten state and then rapidly pressed together.

Butt Joint (Adhesives)

A type of edge joint in which the edge faces of the two adherends is at right angles to the other faces of the adherends.

Button

(1) A globule of metal remaining in an assaying crucible or cupel after fusion has been completed. (2) That part of a weld that tears out in destructive testing of a spot, seam, or projection welded specimen.

Butt Seam Welding

See *seam welding*.

Butt Weld

An erroneous term for a weld in a butt joint. See *butt joint*.

Butt Weld/Butt Joint (Welding)

These terms are used loosely as synonyms. More strictly, the “joint” term refers to the parent component geometry so “butt joint” indicates that the two components are welded edge to edge, usually defined as being at an angle of 135° to 180°. The “weld” term refers to the weld profile so “butt weld” indicates that the weld metal expands across the end face of at least one of the components. Usually there is no confusion for examples of butt welds of butt joints, fillet welds of butt joints and butt welds of T joints. See also *strap joint*.

Butt Welded Tube

Tube formed by rolling or otherwise curving strip to form a near circle and then welding the butting edges together by various welding processes.

Butt Welding

Welding a *butt joint*.

Butting a Tube

Manipulation process in which the two and is formed to a thicker wall and constant outside diameter. The thicker section can accommodate the local increased stresses due to joining processes such as brazing, welding, screwing, or tapping.

Butylene Plastics

Plastics based on resins made by the polymerization of butene or the copolymerization of butene with one or more unsaturated compounds, the butene being the greatest amount by weight.

Butyl Rubber

Butyl is a general-purpose synthetic rubber. There are two types of rubber in this category and both are based on crude oil. The first is polyisobutylene with an occasional isoprene unit inserted in the polymer chain to enhance vulcanization characteristics. The second is the same, except that chlorine is added (approximately 1.2% by weight), resulting in greater vulcanization flexibility and fewer compatibility with general-purpose rubbers.

Butyl rubbers have outstanding impermeability to gases and excellent oxidation and ozone resistance. The chemical inertness is further reflected in lack of molecular-weight breakdown during processing, thus permitting the use of hot-mixing techniques for better polymer/filler interaction.

Flex, tear, and abrasion resistance approach those of natural rubber, and moderate-strength (14.3 MPa) unreinforced compounds can be made at a competitive cost. Butyls lack the toughness and durability, however, of some of the general-purpose rubbers.

Butyl is superior to natural rubber and styrene-butadiene resin (SBR) in resistance to aging and weathering, sunlight, heat, air, ozone and O₂, chemicals, flexing and cut-growth, and in impermeability to gases and moisture. Because of their resistance to deterioration, butyl vulcanizates retain their original properties in actual use longer than either natural rubber or SBR vulcanizates. On heating in an oxidative atmosphere, natural rubber and SBR tend to become hard and brittle, whereas butyl remains unchanged or becomes slightly softer. Butyl can be compounded to have abrasion resistance equal to that of natural rubber and SBR. Butyl also has excellent dielectric properties. In many of its performance properties butyl corresponds to the more expensive synthetics such as the polychloroprenes (neoprene), the polysulfides, and the various nitrile copolymers, although like natural rubber and SBR, butyl alone is neither oil and grease nor flame resistant. In common with other synthetics, butyl has advantages of uniformity and freedom from foreign matter, as compared with natural rubber.

Butyl has relatively high hysteresis loss, and thus unique dynamic properties that made it the preferred rubber in applications requiring shock, vibration, and sound absorption.

Butyl has found a great many applications in the automotive transport, mechanical goods, electrical, chemical, proffed-fabric, building, and consumer-goods fields.

The attribute responsible for the high-volume use of butyl rubber and automotive inner tubes and tubeless tire inner liners is its excellent permeability to air.

Butyl passenger car tires have been successful because the unique dynamic properties of butyl give a remarkably soft, cushioned ride, no squeal on breaking or rounding corners, and higher coefficients of friction between tires and road, which result in shorter stopping distances. The abrasion resistance of butyl tires is compatible to that of other commercial tires.

The resistance of butyl to weathering and to cutting and chipping has been demonstrated in off-the-road machinery and farm tractor tires. Its resistance to weathering, sunlight, and ozone have opened many applications in automotive weatherstrips, windshield gaskets, curtain-wall gaskets and sealers, caulking compounds, and the like. Butyl-coated fabrics are extensively used as convertible tops, tarpaulins, outdoor furniture covers, etc. Such fabrics have been used as liners for irrigation ditches, with the adjacent widths of fabric cemented together with butyl cement at the site to make linings wide enough for large ditches.

Resistance to heat is essential in many butyl applications, such as high-pressure steam hose. Butyl has become the preferred material for curing bags and ladders used in the vulcanization of tires.

Butyl is also used as the inner liner in many tubeless tires, particularly truck tires, because butyl liners remain impermeable even after exposure to the heat of several successive recapping operations.

The outstanding electrical properties of butyl, coupled with its age, ozone, and moisture resistance, have made it useful in many electrical applications. Its resistance to corona and tracking makes it a preferred insulation material for power cable, and because of its heat resistance, butyl-insulated cable can be used to carry more current than cable of equal diameter insulated with SBR or other rubbers. Butyl is also used in electrical encapsulation compounds, as bus-way, factory wire, and communications wire insulation, and in other miscellaneous electrical applications.

Many automotive and mechanical applications take advantage of the ability of butyl to absorb shock, vibration, and noise. These include axle and body bumpers, truck load cushions, boat dock bumpers, bowling alley bumpers, etc. Motor and machinery mounts, bridge pads, drive-shaft insulators, and gasketing applications also benefit from the good resistance of butyl to permanent set from prolonged compression and vibration. Although not usually considered oil resistant, butyl has given years of satisfactory under-the-hood service and spark plug nipples, motor mounts, grommets, radiator hose, and other parts occasionally exposed to oil and grease.

Chemical and heat resistance requirements are satisfied by butyl in applications such as chemical tank linings, gaskets, hose, diaphragms, etc. Butyl is the preferred gasketing material for use in contact with ester-type hydraulic fluids of low flammability. Its acid resistance is used to advantage in dairy hose, and large rubber containers for the bulk transportation of foodstuffs. Chemical, heat, and abrasion resistance are essential in butyl conveyor belts used to transport hot granular solids and chemical plants. Resistance to chemicals and compression set in impermeability to gases are important in butyl food-jar seals and medicine bottle stoppers.

Taylor & Francis

Taylor & Francis Group

<http://taylorandfrancis.com>

“C” Process

See *Croning process*.

CAD

Computer Aided (or assisted) Design.

CAM

Computer Aided (or Assisted) Machining (or Manufacture).

Cable

(1) A flexible electrical insulated conductor or group of conductors twisted (usually multistranded) together for the transmission of electrical energy. (2) Rope or chain, particularly in marine contexts.

Cadmium

Cadmium (symbol Cd) is a silvery-white crystalline metal that has a specific gravity of 8.6, is very ductile, and can be rolled or beaten into thin sheets. It resembles tin and gives the same characteristic cry when bent, but is harder than tin. A small addition of zinc makes it very brittle. It melts at 320°C and boils at 765°C. Cadmium is employed as an alloying element in soft solders and in fusible alloys, for hardening copper, as a white corrosion-resistant plating metal, and in its compounds for pigments and chemicals. It is also used for Ni–Cd batteries and to shield against neutrons in atomic equipment, but gamma rays are emitted when the neutrons are absorbed, and these rays require an additional shielding of lead.

Most of the consumption of cadmium is for electroplating. For a corrosion-resistant coating for iron or steel, a cadmium plate of 0.008 mm is equal in effect to a zinc coat of 0.025 mm. The plated metal has a silvery-white color with a bluish tinge, is denser than zinc, and harder than tin, but electroplated coatings are subject to H₂ embrittlement, and aircraft parts are usually coated by the vacuum process. Cadmium plating is not normally used on copper or brass since copper is electronegative to it, but when these metals are employed next to cadmium-plated steel a plate of cadmium may be used on the copper to lessen deterioration.

Cadmium oxide is used extensively in plastics. In conjunction with barium it forms a compound used to stabilize the color of finished plastics. It is also a major constituent of phosphors used in television tubes.

Cadmium is mutually soluble in a number of other metallic elements. It is combined with several of these elements to form a number of commercial alloys with special properties.

The alloys of cadmium with lead, tin, bismuth, and indium are unique because of their low melting points. For example:

Alloy	Melting Point, °C
33% Cd–67% Sn	176
18% Cd–51.2% Sn–30.6% Pb	145
40% Cd–60% Bi	144
20.2% Cd–25.9% Sn–53.9% Bi	103
10.1% Cd–13.1% Sn–49.5% Bi–27.3% Pb	70
5.3% Cd–12.6% Sn–47.5% Bi–25.4% Pb–19.1% In	47

These fusible alloys are used in applications ranging from fire-detection apparatus to accurate proof casting.

Cadmium has limited use in soft solders combined with tin, lead, and zinc but its major application in the field of joining is for joints requiring higher-temperature strength than can be obtained with the soft solders. Cadmium combined with silver, copper, and zinc forms several brazing filler metals. A typical filler metal contains 35% silver, 26% copper, 21% zinc, 18% cadmium and has a melting point of 608°C. Cadmium (0.7%–1%) is added to copper to make a strong ductile metal that has a high annealing temperature but no serious loss of electrical conductivity. (Trolley wire is an example of its use.) The copper above is called *cadmium copper* or *cadmium bronze*. *Hitenso* is a cadmium bronze of the American Brass Company. It has 35% greater strength than hard-drawn copper and 85% the conductivity of copper. The cadmium bronze known in England as *conductivity bronze*, used for electric wires, contains 0.8% cadmium and 0.6% tin. Tensile strength, hard-drawn, is 586 MPa, and conductivity is 50% that of copper. *Cadmium nitrate*, Cd(NO₃)₂, is a white powder used for making cadmium yellow and fluorescent pigments, and as a catalyst. *Cadmium sulfide*, CdS, is used as a yellow pigment, and when mixed with *cadmium selenide*, CdSe, a red powder, it gives a bright-orange pigment. The sulfide is used for growing *cadmium sulfide crystals* in plates and rods for semiconductor uses. Crystals grown at 1922°F (1050°C) are nearly transparent, but those grown at higher temperatures are dark amber. Cadmium, a carcinogen, can be extremely toxic, and caution is required not to create dust or fumes. Because of its toxicity, use in certain applications—pigments, for example—has declined considerably.

The importance of cadmium in the nuclear field depends on its high thermal neutron capture cross section. By absorbing neutrons, cadmium is employed to control the rate of fission in a nuclear reaction. Cadmium sulfide exhibits both photosensitivity and electroluminescence, that is, it can convert light to electricity and electricity to light.

Finally, the fumes of cadmium, its compounds, and solutions of its compounds are very toxic, and cadmium-plated articles should not be used in food, nor should cadmium-coated articles be welded or used in ovens.

C

Cage

In a bearing, a device that partly surrounds the rolling elements and travels with them, the main purpose of which is to space the rolling elements in proper relation to each other. See also *separator*.

Cake

(1) A copper or copper alloy casting, rectangular in cross section, used for rolling into sheet or strip. (2) A coalesced mass of unpressed metal powder.

Calcareous Coating or Deposit

A layer consisting of a mixture of calcium carbonate and magnesium hydroxide deposited on surfaces being cathodically protected against corrosion because of the increased pH adjacent to the protected surface.

Calcination

Heating ores, concentrates, precipitates, or residues to decompose carbonates, hydrates, or other compounds.

Calcine

(1) A ceramic material or mixture fired to less than fusion for use as a constituent in a ceramic composition. (2) Refractory material, often fireclay, that has been heated to eliminate volatile constituents and to produce desired physical changes.

Calcite

One of the most common and widely diffused materials, occurring in the form of limestones, marbles, chalks, calcareous marls, and calcareous sandstones. It is a *calcium carbonate*, CaCO_3 , and the natural color is white or colorless, but it may be tinted to almost any shade with impurities. The specific gravity is about 2.72 and Mohs hardness 3. The common *black calcite*, containing manganese oxide, often also contains silver in proportions high enough to warrant chemical extraction of the metal.

It is a natural mineral, and in its pure form it is transparent and capable of polarizing light.

Calcium

Calcium (symbol Ca) is a metallic element belonging to the group of alkaline earths. It is one of the most abundant materials, occurring in combination in limestones and calcareous clays. The metal is obtained 98.6% pure by electrolysis of the fused anhydrous chloride. By further subliming, it is obtained 99.5% pure. Calcium metal is yellowish white in color. It oxidizes easily and, when heated in air, burns with a brilliant white light. It has a density of 1.5 g/cm³, a melting point of 838°C, and a boiling point of 1440°C. Its strong affinity for O₂ and sulfur is utilized as a cleanser for nonferrous alloys. As a deoxidizer and desulfurizer it is employed in the form of lumps or sticks of calcium metal or in ferroalloys and Ca–Cu.

Many compounds of calcium are employed industrially in fertilizers, foodstuffs, and medicine. It is an essential element in the formation of bones, teeth, shells, and plants. Oyster shells form an important commercial source of calcium for animal feeds. They are crushed, and the fine flour is marketed for stock feeds and the coarse for poultry feeds. The shell is calcium carbonate.

Edible calcium, for adding calcium to food products, is *calcium lactate*, a white powder of the composition $\text{Ca}(\text{C}_3\text{H}_5\text{O}_3)_2 \cdot 5\text{H}_2\text{O}$, derived from milk. *Calcium lactobionate* is a white powder that readily forms chlorides and other double salts, and is used as a suspending agent in pharmaceuticals. It contains 4.94% available calcium. *Calcium phosphate*, used in the foodstuffs industry and in medicine, is marketed in several forms. *Calcium diphosphate*, known as *phosphate of lime*, is $\text{CaHPO}_4 \cdot 2\text{H}_2\text{O}$, or in anhydrous form. It is soluble in dilute citric acid solutions and is used to add calcium and phosphorus to foods, and as a polishing agent in toothpastes.

Calcium oxide is made by the thermal decomposition of carbonate minerals in tall kilns using a continuous-feed process. Care must be taken during the heating to decompose the limestone at a low enough temperature so that the oxide will slake freely with water. If too high a temperature is used, so-called dead-burnt lime is formed. The oxide is used in high-intensity arc lights (limelights) because of its unusual spectral features and as an industrial dehydrating agent. At high temperatures, lime combines with sand and other siliceous material to form fusible slags; hence, the metallurgical industry makes wide use of it during the reduction of ferrous alloys.

Because of the low cost of *calcium hydroxide*, it is used in many applications where hydroxide ion is needed. Slaked lime is an excellent absorbent for *carbon dioxide* (CO₂) to produce the carbonate. Because of the great insolubility of the carbonate, gases are easily tested qualitatively for CO₂ by passing them through a saturated lime-water solution and watching for a carbonate cloudiness. The hydroxide is also used in the formation of mortar, which is composed of slaked lime (1 volume), sand (3–4 volumes), and enough water to make a thick paste. The mortar gradually hardens because of the evaporation of the water and the cementing action of the deposition of calcium hydroxide, and because of the absorption of CO₂.

Calcium silicide, CaSi, is an electric-furnace product made from lime, silica, and a carbonaceous reducing agent. This material is useful as a steel deoxidizer because of its ability to form calcium silicate, which has a low melting point.

Calcium carbide is a hard, crystalline substance of grayish-black color, used chiefly for the production of **acetylene** gas for welding and cutting torches and for lighting. It is made by reducing lime with coke in the electric furnace, at 2000°C–2200°C. It can also be made by heating crushed limestone to a temperature of about 1000°C, flowing a high-methane natural gas through it, and then heating to 1700°C. The composition is CaC₂, and the specific gravity is 2.26. It contains theoretically 37.5% carbon. When water is added to calcium carbide, acetylene gas is formed, leaving a residue of slaked lime. Although calcium carbide is principally used for making acetylene, this market is shrinking as acetylene is recovered increasingly as a by-product in petrochemical plants. A growing application for calcium carbide is desulfurization deoxidation of iron and steel. It is also a raw material for production of *calcium cyanamide*.

Calcium chloride is a white, crystalline, lumpy or flaky material of composition CaCl₂. The specific gravity is 2.15, the melting point is 1422°F (772°C), and it is highly hygroscopic and deliquescent with rapid solubility in water. The commercial product contains 75%–80% CaCl₂, with the balance chiefly water of crystallization. Some is marketed in anhydrous form for dehydrating gases. It is also sold in water solution containing 40% calcium chloride. Calcium chloride has been used on roads to aid in surfacing, absorb dust, and prevent cracking from freezing. It is also used for accelerating the setting of mortars, but more than 4% in concrete decreases the strength of the concrete. It is also employed as an antifreeze in fire tanks, for brine refrigeration, for storing solar energy, as an anti-ice agent on street pavements, as a food preservative, and in textile and

paper sizes as a gelling agent. In petroleum production, it is used in drilling mud cementing operations, and workover or completion fluids. Calcium chloride is obtained from natural brines and dry lake beds, after *sodium chloride, bromide, and other products are extracted*. The *magnesium–calcium brine* remaining is marketed for dust control or purified into calcium chloride. It is a by-product of sodium bicarbonate production via the Solvay process and is made in small quantities by neutralizing waste of hydrochloric acid with lime or limestone.

Calcium–silicon is an alloy of calcium and silica used as a deoxidizing agent for the elimination of sulfur in the production of steels and cast irons. Steels deoxidized or treated with calcium or calcium and silicon can have better machinability than those deoxidized with aluminum and silicon. It is marketed as low iron, containing 22%–28% calcium, 65%–70% silicon, and 5% maximum iron, and as high iron, containing 18%–22% calcium, 58%–60% silicon, and 15%–20% iron. It comes in crushed form and is added to the molten steel. At the temperature of molten steel, all the calcium passes off and leaves no residue in the steel. *Calcium–manganese–silicon* is another master alloy containing 17%–19% calcium, 8%–10% manganese, 55%–60% silicon, and 10% iron.

Calcium sulfate dihydrate is called *gypsum*. It constitutes the major portion of portland cement, and has been used to help reduce soil alkalinity. A hemihydrate of calcium sulfate, produced by heating gypsum at elevated temperatures, is known under the commercial name *plaster of paris*. When mixed with water, the hemihydrate reforms the dihydrate, evolving considerable heat and expanding in the process, so that a very sharp imprint of the mold is formed. Thus, plaster of paris finds use in the casting of small art objects and mold testing.

Calcium metal is employed as an alloying agent for aluminum-bearing metal, as an aid in removing bismuth from lead, and as a controller for graphitic carbon in cast iron. It is also used as a deoxidizer in the manufacture of many steels, as a reducing agent in preparation of such metals as chromium, thorium, zirconium, and uranium, and as a separating material for gaseous mixtures of N_2 and argon. When added to magnesium alloys (0.25%), it refines the grain structure, reduces their tendency to take fire, and modifies the strengthening heat treatment. It finds use also in the precipitation-hardening Pb–Ca alloys.

Calcium in the biosphere is an invariable constituent of all plants because it is essential for their growth. It is contained both as a structural constituent and as a physiological ion. The calcium ion is able to counteract the toxic effects of potassium, sodium, and magnesium ions. Calcium may also affect the growth of plants because its presence in soil affects the alkalinity of the latter.

Calcium is found in all animals in the soft tissues, in tissue fluid, and in the skeletal structures. The bones of vertebrates contain calcium as calcium fluoride, calcium carbonate, and calcium phosphate. In some lower animals, magnesium replaces either totally or partially the skeletal calcium. The importance of calcium in animals as a structural constituent is based on its abundance and on the low solubility of the three calcium salts just listed. Calcium is also essential in many biological functions of the vertebrates.

Calendered Sheet

Calendering is the process of forming a continuous sheet of controlled size by squeezing a softened thermoplastic material between two or more horizontal rolls. Along with extrusion and casting, calendering is one of the major techniques used to process thermoplastics into film and sheeting. It also is used in the manufacture of

flooring and to apply a plastic coating on paper, textiles, and other supporting materials.

The calendering process is used in the plastics, rubber, linoleum, paper, and metals industries for various roll-forming operations in the manufacture of sheeted materials. This coverage will be concerned only with calendering of thermoplastic materials (plastics and elastomers, the latter of which are calendered in a thermoplastic state prior to vulcanization).

The process consists of five steps: preblending, fluxing, calendering, cooling, and wind-up. Blending of the resin powder with plasticizers, stabilizers, lubricants, colorants, and fillers is usually done in large ribbon blenders. The compound is fluxed, that is heated and worked until it reaches a molten or dough-like consistency.

When a Banbury mill is used, the molten material from it is discharged to a two-roll horizontal mill and thence to the calender either in a continuous strip or in batches. When an extruder is used for fluxing, the extrudate is fed directly to the calender. Alternatively, the preblend can in some cases be fed directly to the calender.

After passage through the calender, the continuous sheet of hot plastic is stripped off the last calender roll with a small, higher-speed stripping roll. The hot sheet is cooled as it travels over a series of cooling drums. The film or sheeting is finally automatically cut into individual sheets or wound up in a continuous roll.

The desired surface finish on the calendered film or sheeting is imparted by the last pair of calender rolls and may range from a high gloss to a heavy matte finish. Extra-high-gloss or special engraved patterns can be made either by having a polished or engraved roll impinge on the last calender roll (contact embossing) or by passing the hot sheeting directly from the calender between an engraved metal roll and a rubber backup roll (in-line embossing). Many attractive patterns are made by these techniques.

The major groups of thermoplastics and elastomers that are calendered into film or sheeting are polyvinyl chloride (PVC) (plasticized and unplasticized) and natural and synthetic rubbers. ABS (acrylonitrile, butadiene, and styrene) polymers, polyolefins, and silicones are also calendered, but in much smaller quantities.

Calendered vinyl is used extensively for floor tile and continuous flooring, rainwear, shower curtains, table covers, pressure-sensitive tape, automotive and furniture upholstery, wall coverings, luminous ceilings, signs and displays, credit cards, etc.

In contrast, calendered rubber—except for some fabric coating—is mainly an intermediate product used in the manufacture of a multitude of articles such as automobile tires, footwear, molded mechanical goods, etc.

In applications that involve the use of calenders for paper and cloth coating, the paper or fabric is fed into the last calender nip so that the plastic or rubber coating is formed on top of the material (calender coating). Frictioning is a variation of this technique by which a thin layer of rubber is squeezed or rubbed into the fabric itself, a technique widely used in the rubber industry for the manufacture of friction tapes and cord fabric for tires.

Production speeds vary greatly with materials, from 10 to 300 fpm (feet per minute). Calenders are heavy, high-precision machines that are made in a variety of designs and with elaborate control equipment that automatically monitors film variations and readjusts the machine to produce the desired thickness.

Calibrate

To determine, by measurement or comparison with a standard, the correct value of each scale reading on a measuring (test) instrument.

C

Calibration

Determination of the values of the significant parameters by comparison with values indicated by a reference instrument or by a set of reference standards.

Calomel Electrode

(1) An *electrode* widely used as a reference electrode of known potential in electrometric measurement of acidity and alkalinity, corrosion studies, voltammetry, and measurement of the potentials of other electrodes. (2) A secondary reference electrode of the composition: Pt/Hg-Hg₂Cl₂/KCl solution. For 1.0 N KCl solution, its potential vs. a hydrogen electrode at 25°C (77°F) at 1 atm is +0.281 V.

Calorie

The quantity of heat required to raise the temperature of 1 g of water by 1°C. The exact value of this depends on the water temperature. The *calorie* (International Table) is 4.186 J. The dietitians calorie, sometimes termed the large calorie or the kilocalorie is 1000 cal.

Calorimeter

An instrument capable of making absolute measurements of energy deposition (or absorbed dose) in a material by measuring its change in temperature and imparting a knowledge of the characteristics of its material construction.

Calorimetry

The measurement in a calorimeter of heat energy relationships.

Calorizing

A process in which steel is coated with aluminum powder and heated to about 1000°C to form an aluminum oxide coating over an aluminum iron intermetallic layer. The coating offers good oxidation resistance up to about 950°C.

Cam Press

A mechanical forming press in which one or more of the slides are operated by cams; usually, a double-action press in which the blankholder slide is operated by cams through which the dwell is obtained.

Camber

(1) Deviation from edge straightness, usually referring to the greatest deviation of side edge from a straight line. (2) The tendency of material being sheared from sheet to bend away from the sheet in the same plane. (3) Sometimes used to denote crown in rolls where the center diameter has been increased to compensate for deflection caused by the rolling pressure. (4) The planar deflection of a flat cable or flexible laminate from a straight line of specified length. A flat cable or flexible laminate with camber is similar to the curve of an unbanked racetrack.

Campaign

The period in which a furnace or other equipment is operated between major overhaul such as the replacement of the refractory lining.

Can

A sheeting of soft metal that encloses a sintered metal billet for the purpose of hot working (hot isostatic pressing, hot extrusion) without undue oxidation.

Canada Balsam

The thin resin produced by Canadian firs. It has a refractive index similar to glass and hence is used as an adhesive for multielement lenses.

Cannel Coal

A variety of coal having some of the characteristics of petroleum, valued chiefly for its quick-firing qualities. It consists of coal-like matter intimately mixed with clay and shale, often containing fossil fishes, and probably derived from vegetable matter in lakes. It is compact in texture, dull black, and breaks along joints, often having an appearance similar to black shale. It burns with a long, luminous, smoky flame, from which it derives its old English name meaning candle.

Canning

(1) A dished distortion in a flat or nearly flat sheet metal surface, sometimes referred to as oil canning. (2) Enclosing a highly reactive metal within a relatively inert material for the purpose of hot working without undue oxidation of the active metal. (3) The materials used for canning nuclear fuel elements are selected for low neutron capture cross section, short half-life, good thermal conductivity, compatibility with the working environment, adequate mechanical properties, and forming characteristics. (4) The containment of foodstuffs and other materials in sealed cans made from tin plated steel, aluminum, or other materials.

Cantilever

A loaded beam supported at one end only.

Capacitance (C)

That property of a system of conductors and dielectrics that permits the storage of electrically separated charges when potential differences exist between the conductors. It is the ratio of a quantity, Q , of electricity to a potential difference, V . A capacitance value is always positive. The units are farads when the charge is expressed in coulombs and the potential in volts: $C = Q/V$.

Capacitor

A capacitor is an electrical device capable of storing electrical energy. In general, a capacitor consists of two metal plates insulated from each other by a dielectric. The capacitance of a capacitor depends primarily upon its shape and size and upon the relative permittivity ϵ_r of the medium between the plates. In vacuum, in air, and in most gases, ϵ_r ranges from one to several hundred.

One classification of capacitors comes from the physical state of their dielectrics, which may be gas (or vacuum), liquid, solid, or a combination of these. Each of these classifications may be subdivided according to the specific dielectric used. Capacitors may be further classified by their ability to be used in AC or DC circuits with various current levels.

TABLE C.1
Major Types of Capacitors

Type	Capacitance	Voltage (Working Voltage, DC), V ^a	Applications
Monolithic ceramics	1 pF–2.2 μ F	50–200	Ultrahigh frequency, RF coupling, computers
Disk and tube ceramics	1 pF–1 μ F	50–1000	General, very high frequency
Paper	0.001–1 μ F	200–1600	Motors, power supplies
<i>Film</i>			
Polypropylene	0.0001–0.47 μ F	400–1600	Television vertical circuits, RF circuits
Polyester	0.001–4.7 μ F	50–600	Entertainment electronics

^a Alternating-current voltage at 60 Hz.

Capacitors are also classified as fixed, adjustable, or variable. Capacitors made with air, gas, or vacuum as the dielectric between plates are constructed with flat parallel metallic plates (or cylindrical concentric metallic plates).

Solid-dielectric types of capacitors use one of several dielectrics such as a ceramic, mica, glass, or plastic film. Alternate plates of metal, or metallic foil, are stacked with the dielectric, or the dielectric may be metal-plated on both sides.

Plastic-film types are capacitors that use dielectrics such as polypropylene, polyester, polycarbonate, or polysulfone with a relative permittivity ranging from 2.2 to 3.2. This plastic film may be used alone or in combination with Kraft paper. The most common electrodes are aluminum or zinc vacuum-deposited on the film, although aluminum foil is also used. Other major types of capacitors can be seen in Table C.1.

The impedance of a capacitor is inversely proportional to the frequency of the voltage impressed; that is, it offers little resistance or impedance to high frequencies, but much to low frequencies.

Capacity

In tensile testing machines, the maximum load and/or displacement for which a machine is designed. Some testing machines have more than one load capacity. These are equipped with accessories that allow the capacity to be modified as desired.

Capacity Number (Cn)

The product of the *Sommerfeld number* and the square of the length-to-diameter ratio of a journal bearing.

Capillarity

The ability of the material to conduct liquids through its pore structure by the force of surface tension.

Capillary Action

(1) The phenomenon of intrusion of a liquid into interconnected small voids, pores, and channels in a solid, resulting from surface tension. (2) The force by which a liquid, in contact with the solid, is distributed between closely fitted faying surfaces of the joint to be brazed or soldered. (3) It is a consequence of surface tension and depends critically on the liquid wetting the solid surface.

Capillary Attraction

(1) The combined force of adhesion and cohesion that causes liquids, including molten metals, to flow between very closely spaced and solid surfaces, even against gravity. (2) In powder metallurgy, the driving force for the infiltration of the pores of a sintered compact by a liquid.

Capped Steel

A type of steel similar to rimmed steel, usually cast in a bottle-top ingot mold, in which the application of a mechanical or a chemical cap renders the rimming action incomplete by causing the top metal to solidify. The surface condition of capped steel is much like that of rimmed steel, but certain other characteristics are intermediate between those of *rimmed steel* and those of *semi-killed steel*.

Capping (of Abrasive Particles)

A mechanism of deterioration of abrasive points in which the points become covered by caps of adherent abrasion debris.

Capping (of Powder Metallurgy Compacts)

Partial or complete separation of a powder metallurgy compact into two or more portions by cracks that originate near the edges of the punch faces and that proceed diagonally into the compact.

Caprolactam

A cyclic amide type of compound containing six carbon atoms. When the range is open, caprolactam is polymerizable into a nylon resin known as type 6 nylon or poly-caprolactam.

Capture Cross Section

The measure of the capability of a material to absorb neutrons without undergoing fission. See *atomic structure*.

Capture Efficiency

See *collection efficiency*.

Car Furnace

A batch-type heat-treating furnace using a car on rails to enter and leave the furnace area. Core furnaces are used for lower stress relieving ranges.

Carat

(1) Units of purity of gold, 24 carat being pure. (2) Metric carat, for gemstones, etc. = 200 mg.

Carbanion Ion

Negatively charged organic compound (ion).

Carbide Tip/Tool

Cutting or forming tools of intermetallic compounds usually made from tungsten, titanium, tantalum, or niobium carbides, or a combination of them, in a matrix of cobalt, nickel, or other metals. Carbide tools are characterized by high hardnesses and compressive strengths and may be coated to improve wear resistance. See also *cemented carbides*.

Carbides

Of the several classes of carbides, only two types need to be considered for engineering applications: the covalent carbides of silicon and

boron, and the interstitial carbides of the transition metals—titanium, zirconium, vanadium, niobium (columbium), tantalum, chromium, molybdenum, and tungsten. All of these may be characterized as hard, refractory materials of extreme chemical inertness. Other carbides such as those of aluminum, iron, and manganese are too reactive to be considered for engineering applications. Chemically, all the inert carbides, with the exception of SiC, are unusual in that they exist in their typical form over a range of composition. In this respect, they are more similar to alloys than true chemical compounds.

Structurally, *interstitial carbides* may be described as metal lattices into which the small carbon atoms have been inserted. In the ideal form, this leads to an fcc (face-centered cubic) structure for all of the metal carbide (MC) types except tungsten carbide (WC), which like the M_2C types has a simple hexagonal structure. B_4C is rhombohedral, and consists of a distorted B lattice in which part of the boron atoms have been replaced by carbon atoms. SiC exists in a number of crystalline polytypes, both cubic (diamond or zinc blend structures) and hexagonal (wurtzite type). All these structures may be described on the basis that every silicon atom is surrounded tetrahedrally by four carbon atoms and that every carbon atom is surrounded tetrahedrally by four silicon atoms.

Properties of carbides that make them unique are their extreme hardness, exceptional corrosion resistance, extreme refractoriness, high Young's modulus of elasticity, and high temperature strength.

The simplest method to produce carbides is a direct combination of the metal with carbon, used exclusively in the preparation of carbides where purity is more important than cost considerations. Most carbides are, however, prepared by reduction of metal oxides with carbon.

With the exception of SiC, all carbide bodies are fabricated using powder metallurgical techniques, that is, sintering and hot pressing. SiC bodies are formed by infiltrating a preformed carbonaceous body with elemental silicon, forming SiC in the shape desired.

Complete pump assemblies have been built to transfer molten metals (corrosion resistance); pipes for heat exchangers (high thermal conductivity); cyclone separators and sandblast nozzles (abrasion resistance); rocket nozzles (refractoriness and erosion resistance); electric-light sources (high melting temperature); and suction box covers for papermaking machines (ability to retain smooth finish without wear).

Several metal carbides mentioned above qualify as engineering ceramics. Most commonly used are B_4C and SiC.

B_4C is noted for its very high hardness and low density—unusual qualities for a brittle ceramic—which qualify this ceramic for lightweight, bulletproof armor plate. The material has the best abrasion resistance of any ceramic, so it is also specified for pressure-blasting nozzles and similar high-wear applications. A limitation of B_4C is its low strength at high temperatures.

Despite its higher cost, SiC is challenging Al_2O_3 , particularly for the more critical applications. SiC is one of the high-temperature, high-strength “superstars” of the engineering ceramics. It is one of the strongest structural ceramics for high-temperature oxidation-resistant service. However, SiC does not easily self-bond. Consequently, many processing variations have been devised to fabricate parts from this material, creating a number of trade-offs in cost, fabric-ability, and properties. The ceramic can be consolidated by hot pressing. Under the combination of high temperature and pressure—with, in some cases, additives that act as bond-forming catalysts—fully dense material can be formed.

The hot-pressed ceramic is extremely strong and tough at high temperatures, but the manufacturing process is limited to simple shapes, bars, or billets. Complex parts made by hot pressing must be machined to shape—a slow and costly process of ultrasonic machining, EDM (if possible), or diamond grinding.

On the other hand, SiC particles can be bonded without pressure by a number of processes, variously called reaction bonding, recrystallization (for SiC), or reaction sintering. With these processes, “green” parts can be dry or isostatically pressed, extruded, slip-cast, or, in some cases, formed by conventional plastic molding techniques such as injection molding, then sintered. Complex shapes, close to finished size can be produced by these techniques, but the ceramic is only about 80% as dense as the hot-pressed counterpart and has lower strength and poorer thermal shock resistance. SiC—either hot pressed or reaction bonded—is not as strong as Si_3N_4 up to about 1427°C; Si_3N_4 grain boundaries soften, or creep, and strength drops. Above 1427°C, SiC is the stronger ceramic. At 1316°C, however, strength of hot-pressed ceramics nearly equals that of reaction-bonded ceramics.

Hot-pressed SiC is harder and more difficult to EDM than Si_3N_4 , which has lower thermal expansion and better thermal shock resistance than SiC. Electrical resistivity of SiC is low at low frequencies and high at high frequencies—an unusual characteristic that qualifies this material as a semiconductor.

Refractory Hard Metals

Refractory hard metals (RHMs) are a ceramic-like class of materials made from metal-carbide particles bonded together by a metal matrix. Often classified as ceramics and sometimes called cemented or sintered carbides, these metals were developed for extreme hardness and wear resistance.

The RHMs are more ductile and have better thermal shock resistance and impact resistance than ceramics, but they have lower compressive strength at high temperatures and lower operating temperatures than most ceramics. Generally, properties of RHMs are between those of conventional metals and ceramics. Parts are made by conventional powder metallurgy compacting and sintering methods. Many metal carbides such as SiC and B_4C are not RHMs but are true ceramics. The fine distinction is in particle binding: RHMs are always bonded together by a metal matrix, whereas ceramic particles are self-bonded. Some ceramics have a second metal phase, but the metal is not used primarily for bonding.

Four RHM systems are used for structural applications and, in most cases, several grades are available within each system. WC with a 3%–20% matrix of cobalt is the most common structural RHM. The low-cobalt grades are used for applications requiring wear resistance; the high-cobalt grades serve where impact resistance is required.

TaC and WC combined in a matrix of nickel, cobalt, and/or chromium provide an RHM formulation especially suited for a combination of corrosion and wear resistance. Some grades are almost as corrosion resistant as platinum. Nozzles, orifice plates, and valve components are typical uses.

TiC in a molybdenum and nickel matrix is formulated for high-temperature service. Tensile and compressive strengths, hardness, and oxidation resistance are as high as 1093°C. Critical parts for welding and thermal metalworking tools, valves, seals, and high-temperature gauging equipment are made from grades of this RHM.

Tungsten–titanium carbide (WTiC_2) in cobalt is used primarily for metal-forming applications such as draw dies, tube-sizing mandrels, burnishing rolls, and flaring tools. The WTiC_2 is a gall resistant phase in the RHM containing WC as well as cobalt.

Carbon

Carbon is a nonmetallic element, symbol C, existing naturally in several allotropic forms, and in combination as one of the most

widely distributed of all the elements. It is quadrivalent, and has the property of forming chain and ring compounds, and there are more varied and useful compounds of carbon than of all the other elements. The black amorphous carbon has a specific gravity of 1.88; the black crystalline carbon known as graphite has a specific gravity of 2.25; the transparent crystalline carbon, as in the diamond, has a specific gravity of 3.51. Amorphous carbon is not soluble in any known solvent. It is infusible, but sublimates at 3500°C, and is stable and chemically inactive at ordinary temperatures. At high temperatures it burns and absorbs O_2 , forming the simple oxides CO and CO_2 ; the latter is the stable oxide present in the atmosphere and a natural plant food. Carbon dissolves easily in some molten metals, notably iron, exerting great influence on them. Steel, with small amounts of chemically combined carbon, and cast iron, with both combined carbon and graphitic carbon, are examples of this.

Carbon occurs as hydrocarbons in petroleum, and as carbohydrates in coal and plant life, and from these natural basic groupings an infinite number of carbon compounds can be made synthetically. Carbon for chemical, metallurgical, or industrial use is marketed in the form of compounds in a large number of different grades, sizes, and shapes; or in master alloys containing high percentages of carbon; or as activated carbons, charcoal, graphite, carbon black, coal-tar carbon, petroleum coke; or as pressed and molded bricks or formed parts with or without binders or metallic inclusions. Natural deposits of graphite, coal tar, and petroleum coke are important sources of elemental carbon.

Combined with carbonaceous binders, such as tars, pitches, and resins, the carbon is compacted by molding or extrusion, and baked at between 816°C and 1649°C to produce what is known as industrial carbon or baked carbon. Conventional industrial graphite (Gr) is made by mixing mined, natural graphite with carbon to produce in effect a C–Gr composite, or baked carbon can be heat treated at about 2985°C, at which temperature the carbon graphitizes.

Manufactured or artificial carbon has a two-phase structure consisting of carbon particles (or grains) in a matrix of binder carbon. Both phases consist essentially of disordered, or uncrystallized, carbon surrounding embryonic carbon crystallites.

Graphites, except for the pyrolytic types, have a two-phase structure similar to that of carbon, but as the result of high-temperature processing contain well-developed graphite crystallites in both phases. These multicrystalline graphites exhibit many of the properties of single-crystal graphite, such as high electrical conductivity, lubricity, and anisotropy. Compared to carbon, graphite has higher electrical and heat conductivity, better lubricity, and is easier to machine. Because of their more favorable properties, graphites have broader application as engineering materials than do carbons. See *graphite*.

Types and Forms of Carbon

Elemental carbon exists in two well-defined crystalline allotropic forms, diamond and graphite. Other forms, which are poorly developed in crystallinity, are charcoal, coke, and carbon black.

Charcoal is prepared by the ignition of wood, sugar, blood, and other carbon-containing compounds in the absence of air. X-ray diffraction studies reveal that it has a graphite structure but is not very well developed in crystallinity. The lack of crystallinity is the result of defects in the crystal structure and the high surface area. In the activated state, charcoal adsorbs gases, liquids, and solids.

Coke, another form of amorphous carbon, is prepared by heating coal in the absence of air. It is used primarily for the reduction of metal oxides to the free metals.

Chemically pure carbon is prepared by the thermal decomposition of sugar (sucrose) in the absence of air. Impurities in the carbon are removed by treatment with chlorine (Cl) gas at red heat. The substance is then washed with water and the low residual chlorine is removed by heating in an atmosphere of H₂ gas.

Carbon-13 is one of the isotopes of carbon, used as a tracer in biologic research where its heavy weight makes it distinguished from other carbon. Carbon-14, or radioactive carbon, has a longer life. It exists in the air, formed by the bombardment of N₂ by cosmic rays at high altitudes, and enters into the growth of plants. The half-life is about 6000 years. It is made from N₂ in a cyclotron.

Carbon fullerenes, such as C₆₀, are a new form of carbon, discovered in the mid-1980s, with considerable potential and diverse applications.

Carbon Fibers/Yarn/Fabric/Wool

These forms are made by pyrolysis of organic precursor fibers in an inert atmosphere. Pyrolysis temperatures can range from 1000°C to 3000°C; higher process temperatures generally lead to higher-modulus fibers. Only three precursor materials, rayon, polyacrylonitrile (PAN), and pitch have achieved significance in commercial production of carbon fibers (see Table C.2). The first high-strength and high-modulus carbon fibers were based on a rayon precursor. These fibers were obtained by being stretched to several times their original length at temperatures above 2800°C. The second generation of carbon fibers is based on a PAN precursor and has achieved market dominance. In their most common form, these carbon fibers have a tensile strength ranging from 2413 to 3102 MPa, a modulus of 0.2 to 0.5 GPa, and a shear strength of 90 to 117 MPa. This last property controls the traverse strength of composite materials. The high-modulus fibers are highly graphitic in crystalline structure after being processed from PAN at temperatures in excess of 1982°C.

TABLE C.2
Carbon Fibers

	Nominal Fiber Modulus (10 ⁶ psi)							
	Pan Fibers				Pitch Fibers			
	30 ^a	40 ^b	40 ^c	50 ^d	70 ^e	50 ^f	75 ^g	100+ ^h
Fiber strength (10 ³ psi)	500	820	650	350	300	275	300	360

Higher-strength fibers obtained at lower temperatures from rayon feature a higher carbon crystalline content. There are also carbon and graphite fibers of intermediate strength and modulus. The third generation of carbon fibers is based on pitch as a precursor. Ordinary pitch is an isotropic mixture of largely aromatic compounds. Fibers spun from this pitch have little or no preferred orientation and hence low strength and modulus. Pitch is a very inexpensive precursor compared with rayon and PAN. High-strength and high-modulus carbon fibers are obtained from a pitch that has first been converted into a mesophase (liquid crystal). These fibers have a tensile strength of more than 2069 MPa, and a Young's modulus ranging from 0.38 to 0.52 GPa.

The average filament diameter of continuous yarn is 0.008 mm. Pitch-based carbon and graphite fibers are expected to see essentially the same applications as the more costly PAN and rayon-derived fibers, for example, ablative, insulation, and friction materials and in metals and resin matrices.

Carbon fibers added to thermoplastic resins provide the highest strength, modulus, heat-deflection temperature, creep, and fatigue—endurance values commercially available in composites. These property improvements, coupled with greatly increased thermal conductivity and low friction coefficients, make carbon fibers ideal for wear and frictional applications where the higher cost can be tolerated. In applications where the abrasive nature of glass fibers wears the mating surface, the softer carbon fibers can be substituted to reduce the wear rate. Carbon fibers can also be used in conjunction with internal lubricants to further improve surface characteristics of most thermoplastic resin systems.

Another useful property of carbon-fiber-reinforced thermoplastics is their low volume and surface resistivities. Most resin systems reinforced with 15% or more carbon fibers can effectively dissipate static charge, which is a problem common to gears, slides, and bearings used in business machine, textile, electrical, and conveying equipment.

Thornel is a yarn made from these filaments for high-temperature fabrics. It retains its strength to temperatures above 1538°C. Carbon yarn is 99.5% pure carbon. It comes in plies from 2 to 30, with each ply composed of 720 continuous filaments of 0.0076 mm diameter. Each ply has a breaking strength of 0.91 kg. The fiber has the flexibility of wool and maintains dimensional stability to 3150°C. *Ucar* is a conductive carbon fabric made from carbon yarns woven with insulating glass yarns with resistivities from 0.2 to 30 Ω for operating temperatures to 288°C. Carbon wool, for filtering and insulation, is composed of pure carbon fibers made by carbonizing rayon. The fibers, 5–50 μm in diameter, are hard and strong, and can be made into rope and yarn, or the mat can be activated for filter use. *Thornel radiotranslucent carbon fibers*, from Amoco Polymers, allow electrical conduction while remaining invisible to x-rays, permitting babies monitoring equipment to stay intact during x-rays and MRIs. *KIIIOOX* fiber, from Amoco Performance Products, Inc., is a pitch-carbon fiber for *prepreg* used to produce composites for thermal management systems in space satellites. *Carbon wool*, for filtering and insulation, is composed of pure-carbon fibers made by carbonizing rayon. *Avceram CS* of FMC Corp., is a composite rayon-silica fiber made with 40% dissolved sodium silicate. A highly heat-resistant fiber, *Avceram CS* is woven into fabric and then pyrolyzed to give a porous interlocked mesh of *carbon silica* fiber, with a tensile strength of 1138 MPa. *Dexsan*, of C.H. Dexter and Sons Co., for filtering hot gases and liquids, is a *carbon filter paper* made from carbon fibers pressed into a paper-like mat, 0.007–0.050 in. (0.18–0.127 mm) thick, and impregnated with activated carbon.

In a process developed by Mitsubishi Gas Chemical Co. (Japan), naphthalene is used as the feedstock for mesophase pitch, called

AR-Resin, to produce carbon fiber. Conoco, Inc. uses a mesophase pitch to make carbon-fiber mat. This pitch has an anisotropic molecular structure rather than the more amorphous one of the PAN precursor.

Carbon brushes for electric motors and generators and *carbon electrodes* are made of carbon in the form of graphite, petroleum coke, lampblack, or other nearly pure carbon, sometimes mixed with copper powder to increase the electric conductivity, and then pressed into blocks or shapes and sintered. Carbon-graphite brushes contain no metals but are made from *carbon-graphite powder* and, after pressing, are subjected to a temperature of 5000°F (2760°C), which produces a harder and denser structure, permitting current densities up to 125 A/in.² (1538 A/m²). *Carbon brick*, used as a lining in the chemical processing industries, is carbon compressed with a bituminous binder and then carbonized by sintering. If the binder is capable of being completely carbonized, the bricks are impervious and dense. *Graphite brick*, made in the same manner from graphite, is more resistant to oxidation than carbon bricks and has a higher thermal conductivity but it is softer. The binder may also be a furfural resin polymerized in the pores. *Karbate No. 1* is a carbon-base brick, and *Karbate No. 2* is a graphite brick. *Impervious carbon* is used for lining pumps, for valves, and for acid-resistant parts. It is carbon- or graphite-impregnated with a chemically resistant resin and molded to any shape. It can be machined. *Porous carbon* is used for the filtration of corrosive liquids and gases. It consists of uniform particles of carbon pressed into plates, tubes, or disks without a binder, leaving interconnecting pores of about 0.001–0.0075 in. (0.025–0.190 mm) in diameter. The porosity of the material is 48%, tensile strength of 1 MPa, and compressive strength about 3.5 MPa. *Porous graphite* has graphitic instead of carbon particles and is more resistant to oxidation but is lower in strength.

Diamond

Diamond is the cubic crystalline form of carbon. When pure, diamond is water clear, but impurities add shades of opaqueness including black. It is the hardest natural material with a hardness on the Knoop scale ranging from 5500 to 7000. It will scratch and be scratched by the hardest anthropogenic material Borozon. It has a specific gravity of 3.5. Diamond has a melting point of around 3871°C, at which point it will graphitize and then vaporize. Diamonds are generally electrical insulators and nonmagnetic. Synthetic diamonds are produced from graphite at extremely high pressures (5,444–12,359.9 MPa) and temperatures from 1204°C to 2427°C. They are up to 0.01 carat in size and are comparable to the quality of industrial diamonds. In powder form, they are used in cutting wheels. Of all diamonds mined, about 80% by weight are used in industry. Roughly 45% of the total industrial use is in grinding wheels. Tests have shown that under many conditions synthetic diamonds are better than mined diamonds in this application.

Composites

Carbon/carbon composites, which comprise carbon fibers in a carbon matrix, are noted for their heat resistance, high-temperature strength, high thermal conductivity, light weight, low thermal expansivity, and resistance to air/fuel mixtures. However, they are costly to produce. Also, they react with oxygen at temperatures above 800°F (427°C), necessitating oxygen-barrier coatings. *Silicon carbide*, 0.005–0.007 in. (0.127–0.178 mm) thick, serves as such a coating for applications in the nose cone and wing leading edges of the Space Shuttle. Other uses include the brakes of large commercial aircraft, clutches and brakes of Formula One race cars, and rocket nozzles.

Carbon films, usually made by chemical vapor deposition (CVD) at 2012°F (1100°C), can strengthen and toughen *ceramic-matrix composites* but are not readily adaptable to coating fibers, platelets,

or powder. The Japanese have developed what is said to be a more economical method using silicon carbide and other ceramics. Nanometer- to micrometer-thick films are formed on these forms including silicon carbide single crystals, by treating them with water under pressure at 572°F–1472°F (300°C–800°C). This treatment transforms the surface layer to carbon.

The so-called carbons used for electric-light **arc electrodes** are pressed from coal-tar carbon, but are usually mixed with other elements to bring the balance of light rays within the visible spectrum. Solid carbons have limited current-carrying capacity, but when the carbon has a center of metal compounds such as the fluorides of the rare earths, the current capacity is greatly increased. It then forms a deep positive crater in front of which is a flame five times the brilliance of that with a low-current arc. *The sunshine carbon*, used in electric-light carbons to give approximately the same spectrum as some light, is molded coal-tar carbon with a core of cerium metals to introduce more blue into the light. *Arc carbons* are also made to give other types of light, and to produce special rays for medicinal and other purposes. *B carbon*, of National Carbon Co., Inc., contains iron in the core and gives a strong emission of rays which are the antirachitic radiations. The light seen by the eye is only one-fourth the total radiation since the strong rays are invisible. *C carbon* contains iron, nickel, and aluminum in the core and gives off powerful lower-zone ultraviolet rays. It is used in light therapy and for industrial applications. *E carbon*, to produce penetrating infrared radiation, contains strontium. *Electrode carbon*, used for arc furnaces, is molded in various shapes from carbon paste.

Carbides

Carbon forms binary compounds known as carbides with elements less electronegative than carbon (C–H₂ compounds are excluded). Effectively then, carbides are composed of metal-carbon compounds if boron and silicon are included among the normal metals. Essentially no volatile compounds (except AlC) are known because decomposition sets in at higher temperatures before volatilization of the carbide as such can occur.

Most carbides can be prepared by heating a mixture of the powdered metal and carbon, usually to high temperatures, but not necessarily as high as the melting point. Generally, the same result is possible by heating a mixture of the oxide of the metal with carbon.

It is useful to classify carbides as ionic (salt-like), metallic (interstitial), and covalent. The more electropositive elements (groups I, II, and III, and to some extent, members of the lanthanide and actinide series of the periodic system) form ionic carbides with transparent (or salt-like) crystals.

Highly refractory covalent carbides are formed with silicon and boron. SiC (diamond structure) is formed from a mixture of SiO₂ and coke. The very hard B₄C can be made similarly from its oxide; it is unusual both structurally and in having a fairly high electrical conductivity.

The carbides of chromium, manganese, iron, cobalt, and nickel are intermediate between the interstitial and covalent types, but are much nearer the former in properties. The presence of Fe₃C in iron is an important factor in the properties of steel.

Mechanical/Thermal/Electrical/Other Properties

Compared to metals and most polymers, room-temperature tensile strengths of conventional carbon and graphite are low, ranging from 6.8 to 9.16 MPa. Compressive strengths range from 20.6 to 54.9 MPa. These are generally with-grain values (i.e., specimen length is parallel to the grain).

Carbon and graphite do not have a true melting point. They sublime at 4399°C. Conventional graphite have exceptionally high thermal conductivity at room temperature, whereas carbon has only fair conductivity. Conductivity with the grain in graphite is comparable to that of aluminum; across the grain it is about the same as brass. Conductivity increases with temperature up to about 0°C; it then remains relatively high, but decreases slowly over a broad temperature range, before it drops sharply. In pyrolytic graphite, thermal conductivity with the grain approaches that of copper; across grain, it serves as a thermal insulator and is comparable to that of ceramics.

Thermal expansion of carbon and graphite is quite low (1 to $1.5 \times 10^{-6}/^\circ\text{F}$)—less than one third that of many metals. Expansion of graphite across grain increases with increasing density, whereas along the grain it decreases with increasing density. But expansion increases in both directions with increasing temperatures.

The electrical characteristics associated with carbon and graphite use as electrodes or anodes are relatively well known. Carbon and graphite are actually semiconductors, with their electrical resistivity, or conductivity, falling between those of common metals and common semiconductors. At temperatures approaching absolute zero, carbon and graphite have few conducting electrons, the number increasing with increasing temperature. Thus, electrical resistivity decreases with increasing temperature. On the other hand, although increasing electron density tends to reduce resistivity as temperature rises, scattering effects may become dominant at certain temperatures in the range of 982°C and thus modify or even reverse this trend. Pyrolytic graphite with its higher density has improved electrical conductivity (along the grain). Further, its high degree of anisotropy results in a high degree of electrical resistivity across the grain.

Other properties of graphite are excellent lubricity and relatively low surface hardness; carbon has fair lubricity and relatively high surface hardness. Further, certain types of carbon graphitize relatively easily; others do not. Consequently, a wide variety of carbon, C-Gr, and graphite materials are available, each designed to provide specific types of surface characteristics for such uses as bearings and seals. Grades are also available impregnated with a wide variety of substances, from synthetic resin or oil to a bearing metal.

The nuclear grades of carbon and graphite are of exceptionally high purity. As a moderator and reflector in nuclear reactors, they have no equal because of their low thermal neutron absorption cross section and high scattering cross section coupled with high strength at elevated temperatures and thermal stability in nonoxidizing environments. In general, the properties of carbon and graphite are improved by exposure to nuclear radiation. Hardness and strength increase while thermal and electrical conductivity decrease.

Applications

The free element of carbon has many uses, ranging from ornamental applications of the diamond in jewelry to the black-colored pigment of carbon black in automobile tires and printing inks. Another form of carbon, graphite, is used for high-temperature crucibles, arc-light and dry-cell electrodes, lead pencils, and as a lubricant. Charcoal, an amorphous form of carbon, is used as an absorbent for gases and as a decolorizing agent.

The compounds of carbon find many uses. CO_2 is used for the carbonation of beverages, for fire extinguishers, and in the solid state as a refrigerant. CO finds use as a reducing agent for many metallurgical processes. Carbon tetrachloride and carbon disulfide are important solvents for industrial uses. Gaseous dichlorodifluoromethane, commonly known as *Freon*, is used in refrigeration devices. Calcium carbide is used to prepare acetylene, which is used

for the welding and cutting of metals as well as for the preparation of other organic compounds. Other metal carbides find important uses as refractories and metal cutters.

Carbon nanotubes may one day be used to construct extremely small-scale circuits. Scientists have observed ballistic conductance—electrons passing through a conductor without heating it—at room temperature in 5 μm carbon nanotubes. Because the nanotubes remain cool, extremely large current densities can flow through them.

The most common use of manufactured carbon is as sliding elements in mechanical devices. It is used as the primary rubbing face in most mechanical seals. Used as a brush, it transfers electrical current to the rotating commutator on small electric motors. Carbon vanes, piston rings, or cylinder liners are used in most small air pumps and drink-dispenser pumps. Carbon is also used for pistons in chemical-metering pumps and for metering valves in gasoline pumps. All these applications require the carbon to slide on metal with a coefficient of friction below 0.2 and a wear rate below 0.001 in. per million inches rubbed.

Bearings are another significant application area for manufactured carbon. In many cases, characteristics of the carbon bearing are tailored to satisfy a wide range of requirements. This is done by impregnating the porous, as-baked or as-graphitized carbon with various materials—for example, resin, babbitt, copper, or glass—or by combining impregnation with chemical conversion of the carbon surface (to hard SiC).

These self-lubricating materials are particularly suited for environments containing dust or lint, repeated steam cleaning, solvents or corrosive fluids, low or high temperatures, high static loads, or hard vacuums. Some of these conditions require impregnants in the carbon material. Other applications using manufactured carbon bearings are those inaccessible for lubrication or where product contamination (from lubricants) cannot be tolerated.

Carbon Arc Cutting (CAC)

An arc cutting process in which metals are severed by melting them with the heat of an arc between a carbon electrode and the base metal. To melt the metal along the line of cut.

Carbon Arc Welding (CAW)

An arc welding process that produces coalescence of metals by heating them with an arc between a carbon electrode and the work or struck between two carbon electrodes. No shielding is used although gases produced by the burning of the carbon may offer protection.

Carbon Black

An amorphous powdered carbon resulting from the incomplete combustion of a gas, usually deposited by contact of the flame on a metallic surface, but also made by the incomplete combustion of the gas and a chamber. The carbon black made by the first process is called *channel black*, taking the name from the channel iron used as the depositing surface. The modern method, called the *impingement* process, uses many small flames with the fineness of particles size controlled by flame size. The air-to-gas ratio is high, giving oxidized surfaces and acid properties. No water is used for cooling, keeping the ash content low. The supergrade of channel black has a particle size as low as 512 $\mu\text{in.}$ (13 μm) and a pH of 3–4.2. Carbon black made by other processes is called *soft black* and is weaker in color strength, not so useful as a pigment. *Furnace black* is made

with a larger flame in a confined chamber with the particles settling out in cyclone chambers. The particle size is oily, and the pH is high. Black Pearl 3700, 4350, and 4750 are high-purity furnace blacks from Cabot Corp. The 3700, with cleanliness and cable smoothness and cleanliness similar to acetylene, is intended as an alternative to the latter for semiconductor cable shields. The 4350 and 4750 could become the first furnace blacks used for single-service food packaging because of their low polyaromatic-hydrocarbon content and better dispersion and impact resistance than selective channel blacks approved for this application.

Because it possesses useful ultraviolet protective properties, it is also much used in molding compounds intended for outside weathering applications.

Carbon black from clean artificial gas is a glossy product with an intense color, but all the commercial carbon black is from natural gas. The finer grades of channel black are mostly used for color pigment, in paints, polishes, carbon paper, and printing and drawing inks. The larger use of carbon black is in automotive tires to increase the wear resistance of the rubber. The blacker blacks have a finer particle size than the grayer blacks, hence have more surface and absorptive capacity and compounding with rubber. Channel black is valued for rubber compounding because of its low acidity and low grit content.

In rubber compounding, the carbon black is evenly dispersed to become intimately attached to the rubber molecule. The fineness of the black determines the tensile strength of the rubber, the structure of the carbon particle determines the modulus, and the pH determines the cure behavior. Furnace blacks have a basic pH which activates the accelerator, and delaying-action chemicals are thus needed, but fine furnace blacks impart abrasion resistance to the rubber. Furnace black made with a confined flame with limited air has a neutral surface and a low volatility. Fineness is varied by temperature, size of flame, and time. Carbonate salts raise the pH. Most of the channel black for rubber compounding is made into dust-free pellets. *Color-grade black* for inks and paints is produced by the channel process or the impingement process. In general, carbon black for reinforcement has small particle size, and the electrically conductive grades, *CF carbon black* and *CC carbon black*, conductive furnace and conductive channel, have large particle sizes.

Acetylene black is a carbon black made by heat decomposition of acetylene. It is more graphite than ordinary carbon black with colloidal particles linked together in an irregular lattice structure and has high electrical conductivity and high liquid-absorption capacity. Particle size is intermediate between that of channel black and furnace black, with low ash content, nonoiliness, and a pH of 6.5. It is valued for use in dry cells and lubricants. *Ucet*, of Union Carbide Corp., is in the form of agglomerates of irregular fine crystals. The greater surface area gives higher thermal and electrical conductivity and high liquid absorption.

For electrically *conductive rubber*, the mixing of the black with the rubber is regulated so that carbon chain connections are not broken. Such conductive rubber is used for tabletops, conveyor belts, and coated filter fabrics to prevent static buildup. Carbon blacks are also made from liquid hydrocarbons, and from anthracite coal by treatment of the coal to liberate hydrogen and carbon monoxide and then high-temperature treatment with chlorine to remove impurities. The black made from anthracite has an open pore structure useful for holding gases and liquids.

NASA Propulsion Laboratories has determined that the addition of *Shawanigen carbon black* markedly increases the life of amorphous-carbon or graphite anodes in rechargeable lithium-ion electrochemical cells.

Carbon Dioxide

Also called *carbonic anhydride*, and in its solid state, *dry ice*. A colorless, odorless gas of composition CO_2 , which liquefies at -85°F (-65°C) and solidifies at -108.8°F (-78.2°C). Release of CO_2 into the atmosphere by the burning of fossil fuels is said to be causing global warming by the process known as the *greenhouse effect*. It is recovered primarily as a by-product of the steam reforming of natural gas to make hydrogen or synthesis gas in petroleum and fertilizer plants. Smaller quantities are obtained by purifying flue gases generated from burning hydrocarbons or lime and from distilleries. Its biggest uses are captive, as a chemical raw material for making urea and in enhanced oil recovery operations in petroleum production. Merchant CO_2 is more than 99.5% pure, with less than 500 ppm (parts per million) of nonvolatile residues. In liquid form it is marketed in cylinders and is used in fire extinguishers, in spray painting, in refrigeration, for inert atmospheres, for the manufacture of *carbonated beverages*, and in many industrial processes. It is also marketed as dry ice, a white, snow-like solid used for refrigeration and transporting food products. *Cardox* is a trade name of Cardox Corp. for liquid carbon dioxide in storage units at 30 lb/in.² (0.21 MPa) pressure for fire-fighting equipment. Other uses include hardening of foundry cores, neutralization of industrial wastes, and production of salicylic acid for aspirin. Carbon dioxide is a key lasing gas and *carbon dioxide lasers* and is also used as a shielding gas in some MIG welding applications for steel, and as a foaming agent in producing plastic foam products. It can behave as a *supercritical fluid*, in which state it can be used to foam plastics and extract hazardous substances and waste treatment processes and in soil remediation. CO_2 is used to wash brownstock in the pulp and paper industry, thereby sending cleaner pulp onto bleaching. In cooling systems, it is an alternative to halogenated-carbon refrigerants, CO_2 “*snow*,” pellets that is, is used to cool freshly laid eggs, cuts of meat and poultry, and flour in baking. Dry ice pellets are blasted on molds to clean them of plastic residuals. **Liquid carbon dioxide** is used in SuperFuge, an immersion system by Deflex Corp. to rid products of surface contaminants.

Carbon Dioxide Process (Sodium Silicate/ CO_2)

In foundry practice, a process for hardening molds or cores in which carbon dioxide gas is blown through dry clay-free silica sand to precipitate silica in the form of a gel from the sodium silicate binder.

Carbon Dioxide Welding

A *gas metal-arc welding* (GMAW) process for steel in which carbon dioxide is fit into the arc vicinity to protect the weld zone from atmospheric contamination. Carbon dioxide is effectively inert in these circumstances and its choice, rather than argon, arises from its favorable effect on arc characteristics as well as the economic factor.

Carbon Edges

Carbonaceous deposits in a wavy pattern along the edges of a steel sheet or strip; also known as *snaky edges*.

Carbon Electrode

A nonfiller material electrode used in arc welding or cutting, consisting of a carbon or graphite rod, which may be coated with copper or other coatings.

Carbon Equivalent

(1) The measure of the effect of one or more alloying elements in cast iron or steel expressed in terms of the amount of carbon that would have the same effect. For example, the alloying elements in steel effect characteristics such as hardenability, and hence weldability, or microstructure in a way which reinforces or detracts from the effect of carbon. The element can therefore be ascribed as a factor reflecting its potency relative to carbon, taken as unity. This factor is termed the carbon equivalent of the element. In any iron or steel, individual alloy contents multiplied by their respective carbon equivalents can be added together to provide a total carbon equivalent for the material. (2) One of a number of formulae for predicting weldability of low alloy steels is:

$$\text{Carbon Equivalent} = C + \left(\frac{\text{Mn}}{20} \right) + \left(\frac{\text{Ni}}{15} \right) + \left(\frac{\text{Cr, Mo, V}}{10} \right)$$

Also see *Schaeffler Diagram* for an example of carbon equivalents related to microstructure. (3) For cast iron, an empirical relationship of the total carbon, silicon, and phosphorus contents expressed by the formula:

$$\text{CE} = \%C + 0.3(\%Si) + 0.33(\%P) - 0.027(\%Mn) + 0.4(\%S)$$

(4) For rating of weldability:

$$\text{CE} = C + \frac{\text{Mn}}{6} + \frac{\text{Ni}}{15} + \frac{\text{Cu}}{15} + \frac{\text{Cr}}{5} + \frac{\text{Mo}}{5} + \frac{\text{V}}{5}$$

Carbon Extraction Replica

See *extraction replica*.

Carbon Fiber

(1) Fiber produced by the pyrolysis of organic precursor fibers, such as rayon, polyacrylonitrile (PAN), and pitch, in an inert environment. The term is often used interchangeably with the term graphite; however, carbon fibers and graphite fibers differ. The basic differences lie in the temperature at which the fibers are made and heat-treated, and in the amount of elemental carbon produced. Carbon fibers typically are carbonized in the region of 1315°C (2400°F) and assay at 93%–95% carbon, while graphite fibers are graphitized at 1900°C–2480°C (3450°F–4500°F) and assay at more than 99% elemental carbon. (2) A filament comprised of nearly pure carbon typically up to 10 μm diameter used for reinforcement epoxy or other plastics to form carbon fiber composite materials. See also *pyrolysis*.

Carbon Flotation

In casting, segregation in which free graphite has separated from the molten iron. This defect tends to occur at the upper surfaces of the cope of the castings.

Carbon Monoxide

Carbon monoxide (CO) is a product of incomplete combustion, and is very reactive. It is one of the desirable products in synthesis gas

for making chemicals; the synthesis gas made from coal contains at least 37% CO. It is also recovered from top-blown O₂ furnaces in steel mills. It reacts with H₂ to form methanol, which is then catalyzed by zeolites into gasoline. Acetic acid is made by methanol carbonylation, and acrylic acid results from the reaction of CO, acetylene, and methanol. CO forms a host of neutral, anionic, and cationic carbonyls, with such metals as iron, cobalt, nickel, molybdenum, chromium, rhodium, and ruthenium. These metals are from groups I, II, VI, VII, and VIII of the periodic table. The metal carbonyls can be prepared by the direct combination of the metal with CO, although several of the compounds require fairly high pressures. The metal carbonyls react with the halogens to produce metal carbonyl halides. With H₂, a similar reaction takes place to form metal carbonyl hydrides.

Nickel carbonyl finds application in purification and separation of nickel from other metals. Iron carbonyl has been used in anti-knock gasoline preparations and to prepare high-purity iron metal.

CO is an intense poison when inhaled and is extremely toxic even in the small amounts from the exhausts of internal-combustion engines.

With chlorine, in the presence of sunlight, CO forms highly poisonous phosgene, COCl₂; with sulfur, carbonyl sulfide, COS, is obtained.

Carbon Nitride

Traditional materials synthesis techniques, which require high-temperature conditions to facilitate diffusion of atoms in the solid state, generally preclude the rational assembly of atoms since the products are restricted to those phases stable at high temperature. For example, heating graphite in molecular N₂ does not provide carbon nitride (C–N) solids. However, binary C–N solids are desirable materials to prepare and study because they may possess extreme hardness and high thermal conductivity. Extreme hardness is important in thin-film coatings of cutting tools used for machining and in bearing surfaces used in a variety of high-performance mechanical devices, whereas high thermal conductivity is important to the fabrication of advanced microelectronics devices. To overcome the limitations imposed by classical methodologies of solid-state chemistry and provide access to these potentially exciting materials requires better control of the reactants and reactions that might lead to C–N solids. A new experimental approach that meets these requirements and has provided access to C–N materials utilizes pulsed-laser evaporation of graphite to generate reactive carbon fragments and an atomic N₂ beam as a source of N₂ that can readily react with the carbon fragments.

The atomic N₂ beam is generated by using a radio-frequency discharge within an Al₂O₃ nozzle through which N₂ seeded in helium flows. This process produces a very high flux of atomic N₂. Furthermore, by varying the N₂:He ratio and the radio-frequency power, it is possible to control both the flux and energy of this critical reactant. Hence, this synthetic approach provides a ready means of producing reactants that are free from impurities and that have controllable energies.

Structure

The structural properties of the C–N materials produced by the laser ablation approach have been investigated and show that carbon and N₂ are bound covalently within this solid but cannot provide information about the three-dimensional structure. Diffraction ring patterns suggest that a single crystalline C–N phase was obtained by using the new synthetic strategy.

Other Key Properties

The new C–N materials also exhibit interesting physical properties that may be attractive for high-performance engineering applications. Qualitative scratch tests indicate that C–N materials produced by the new laser ablation technique are hard. For example, rubbing C–N and hard amorphous carbon surfaces against one another produces damage in the carbon but not the C–N material.

Studies have shown that C–N is an excellent electrical insulator, and that these electrical properties are stable to thermal cycling. Because C–N is also expected to exhibit good thermal conductivity, it could be an attractive candidate for the dielectric in advanced microelectronic devices where thermally conducting electrical insulators are needed to enable further miniaturization of devices.

Carbon Potential

A measure of the ability of an environment containing active carbon to alter or maintain, under prescribed conditions, the carbon level of the steel. In any particular environment, the carbon level attained will depend on such factors as temperature, time, and steel composition.

Carbon Refractory

A manufactured refractory comprised substantially or entirely of carbon (including graphite).

Carbon Restoration

Replacing the carbon lost in the surface layer from previous processing of the steel by carburizing this layer to substantially the original carbon level. Sometimes called re-carburizing.

Carbon Steel

Carbon (C) steel, also called plain carbon steel, is a malleable, iron-based metal containing carbon, small amounts of manganese, and other elements that are inherently present. The old shop names, machine steel and machinery steel, are still used to mean any easily worked low-carbon steel. By definition, plain carbon steels are those that contain up to about 1% carbon, not more than 1.65% manganese, 0.60% silicon, and 0.60% copper, and only residual amounts of other elements, such as sulfur (0.05% max) and phosphorus (0.04% max). They are identified by means of a four-digit numerical system established by the American Iron and Steel Institute (AISI). The digits are preceded by either “AISI” or “SAE.” The first digit is the number 1 for all carbon steels. A 0 after the 1 indicates non-resulfurized grades, a 1 for the second digit indicates resulfurized grades, and the number 2 for the second digit indicates resulfurized and rephosphorized grades. The last two digits give the nominal (middle of the range) carbon content, in hundredths of a percent. For example, for grade 1040, the 40 represents a carbon range of 0.37%–0.44%. If no prefix letter is included in the designation, this steel was made by the basic open-hearth, basic O₂, or electric furnace process. The prefix B stands for the acid Bessemer process, which is obsolete, and the prefix M designates merchant quality. The letter L between the second and third digits identifies leaded steels, and the suffix H indicates that this steel was produced to hardenability limits. See Table C.3.

For all plain carbon steels, carbon is the principal determinant of many performance properties. Carbon has a strengthening and

hardening effect. At the same time, it lowers ductility, as evidenced by a decrease in elongation and reduction of area. In addition, increasing carbon content decreases machinability and weldability, but improves wear resistance. The amount of carbon present also affects physical properties and corrosion resistance. With an increase in carbon content, thermal and electric conductivity decline, magnetic permeability decreases drastically, and corrosion resistance is less.

Carbon steels may be specified by chemical composition, mechanical properties, method of oxidation, or thermal treatment (and the resulting microstructure). Carbon steels are available in most wrought mill forms, including bar, sheet, plate, and tubing. Sheet is primarily a low-carbon-steel product, but virtually all grades are available in bar and plate. Plate, usually a low-carbon or medium-carbon product, is used mainly in the hot-finished condition, although it also can be supplied heat-treated. Bar products, such as rounds, squares, hexagonals, and flats (rectangular cross sections), are also mainly low-carbon and medium-carbon products and are supplied hot-rolled or hot-rolled and cold-finished. Cold finishing may be by drawing (cold-drawn bars are the most widely used); turning (machining) and polishing; drawing, grinding, and polishing; or turning, grinding, and polishing. Bar products are also available in various quality designations, such as merchant quality (M), cold-forging quality, cold-heading quality, and several others. Sheet products also have quality designations as noted in low-carbon steels, which follow. Plain carbon steels are commonly divided into three groups, according to carbon content: low carbon, up to 0.30%; medium carbon, 0.31%–0.55%; and high carbon, 0.56%–1%.

Low-carbon steels are the grades AISI 1005–1030. Sometimes referred to as mild steels, they are characterized by low strength and high ductility, and are nonhardenable by heat treatment except by surface-hardening processes. Because of their good ductility, low-carbon steels are readily formed into intricate shapes. These steels are also readily welded without danger of hardening and embrittlement in the weld zone. Although low-carbon steels cannot be through-hardened, they are frequently surface-hardened by various methods (carburizing, carbonitriding, and cyaniding, for example) that diffuse carbon into the surface. Upon quenching, a hard, wear-resistant surface is obtained.

Low-carbon sheet and strip steels (1008–1012) are widely used in cars, trucks, appliances, and many other applications. Hot-rolled products are usually produced on continuous hot strip mills. Cold-rolled products are then made from the hot-rolled products, reducing thickness and enhancing surface quality. Unless the fully work-hardened product is desired, it is then annealed to improve formability and temper-rolled to further enhance surface quality. Hot-rolled sheet and strip and cold-rolled sheet are designated commercial quality (CQ), drawing quality (DQ), drawing quality special killed (DQSK), and structural quality (SQ). The first three designations refer, respectively, to steels of increasing formability and mechanical property uniformity. SQ, which refers to steels produced to specified ranges of mechanical properties and/or hardenability values, does not pertain to cold-rolled strip, which is produced to several tempers related to hardness and bendability. Typically, the hardness of CQ hot-rolled sheet ranges from Rb 40 to 75 and tensile properties range from ultimate strengths of 276 to 469 MPa, yield strengths of 193 to 331 MPa and elongations of 14% to 43%. For DQ hot-rolled sheet: Rb 40 to 72, 276 to 414 MPa, 186 to 310 MPa, and 28% to 48%, respectively. For CQ cold-rolled sheet: Rb 35 to 60, 290 to 393 MPa, 159 to 262 MPa, and 30% to 45%. And for DQ cold-rolled sheet: Rb 32 to 52, 262 to 345 MPa, 138 to 234 MPa, and 34% to 46%.

Low-carbon steels 1018–1025 in cold-drawn bar (16–22 mm thick) have minimum tensile properties of about 483 MPa ultimate

TABLE C.3

Composition Ranges and Limits for AISI-SAE Standard Carbon Steels—Structural Shapes, Plate, Strip, Sheet, and Welded Tubing

AISI-SAE Designation	UNS Designation	Heat Composition Ranges and Limits, ^a %	
		C	Mn
1006	G10060	0.08 max	0.25–0.45
1008	G10080	0.10 max	0.25–0.50
1009	G10090	0.15 max	0.60 max
1010	G10100	0.08–0.13	0.30–0.60
1012	G10120	0.10–0.15	0.30–0.60
1015	G10150	0.12–0.18	0.30–0.60
1016	G10160	0.12–0.18	0.60–0.90
1017	G10170	0.14–0.20	0.30–0.60
1018	G10180	0.14–0.20	0.60–0.90
1019	G10190	0.14–0.20	0.70–1.00
1020	G10200	0.17–0.23	0.30–0.60
1021	G10210	0.17–0.23	0.60–0.90
1022	G10220	0.17–0.23	0.70–1.00
1023	G10230	0.19–0.25	0.30–0.60
1025	G10250	0.22–0.28	0.30–0.60
1026	G10260	0.22–0.28	0.60–0.90
1030	G10300	0.27–0.34	0.60–0.90
1033	G10330	0.29–0.36	0.70–1.00
1035	G10350	0.31–0.38	0.60–0.90
1037	G10370	0.31–0.38	0.70–1.00
1038	G10380	0.34–0.42	0.60–0.90
1039	G10390	0.36–0.44	0.70–1.00
1040	G10400	0.36–0.44	0.60–0.90
1042	G10420	0.39–0.47	0.60–0.90
1043	G10430	0.39–0.47	0.70–1.00
1045	G10450	0.42–0.50	0.60–0.90
1046	G10460	0.42–0.50	0.70–1.00
1049	G10490	0.45–0.53	0.60–0.90
1050	G10500	0.47–0.55	0.60–0.90
1055	G10550	0.52–0.60	0.60–0.90
1060	G10600	0.55–0.66	0.60–0.90
1064	G10640	0.59–0.70	0.50–0.80
1065	G10650	0.59–0.70	0.60–0.90
1070	G10700	0.65–0.76	0.60–0.90
1074	G10740	0.69–0.80	0.50–0.80
1078	G10780	0.72–0.86	0.30–0.60
1080	G10800	0.74–0.88	0.60–0.90
1084	G10840	0.80–0.94	0.60–0.90
1085	G10850	0.80–0.94	0.70–1.00
1086	G10860	0.80–0.94	0.30–0.50
1090	G10900	0.84–0.98	0.60–0.90
1095	G10950	0.90–1.04	0.30–0.50
1524 ^b	G15240	0.18–0.25	1.30–1.65
1527 ^b	G15270	0.22–0.29	1.20–1.55
1536 ^b	G15360	0.30–0.38	1.20–1.55
1541 ^b	G15410	0.36–0.45	1.30–1.65
1548 ^b	G15480	0.43–0.52	1.05–1.40
1552 ^b	G15520	0.46–0.55	1.20–1.55

^a Limits on phosphorus and sulfur contents are typically 0.040% maximum phosphorus and 0.050% maximum sulfur. Silicon contents range from 0.080% to approximately 2%. Steels listed in this table can be produced with additions of lead or boron. Leded steels typically contain 0.15%–0.35% lead and are identified by inserting the letter “L” in the designation—11L17; boron steels can be expected to contain 0.0005%–0.003% boron and are identified by inserting the letter “B” in the designation—15B41.

^b Formerly designated 10xx grade.

strength, 413 MPa yield strength, and 18% elongation. Properties decrease somewhat with increasing section size, to, for example, 379 MPa, 310 MPa and 15%, respectively, for 50–76 mm cross sections.

Medium-carbon steels are the grades AISI 1030–1055. They usually are produced as killed, semikilled, or capped steels, and are hardenable by heat treatment. However, hardenability is limited to thin sections or to the thin outer layer on thick parts. Medium-carbon steels in the quenched and tempered condition provide a good balance of strength and ductility. Strength can be further increased by cold work. The highest hardness practical for medium-carbon steels is about 550 Bhn (Rockwell C55). Because of the good combination of properties, they are the most widely used steels for structural applications, where moderate mechanical properties are required. Quenched and tempered, their tensile strengths range from about 517 to over 1034 MPa.

Medium-carbon steel 1035 in cold-drawn bar 16–22 mm thick has minimum tensile properties of about 586 MPa ultimate strength, 517 MPa yield strength, and 13% elongation. Strength increases and ductility decreases with increasing carbon content, to, for example, 689 MPa, 621 MPa, and 11%, respectively, for medium-carbon steel 1050. Properties decrease somewhat with increasing section size, to, for example, 483 MPa, 414 MPa, and 10%, respectively, for 1035 steel 50–76 mm cross sections.

High-carbon steels are the grades AISI 1060–1095. They are, of course, hardenable with a maximum surface hardness of about Rockwell C64 achieved in the 1095 grade. These steels are thus suitable for wear-resistant parts. So-called spring steels are high-carbon steels available in annealed and pretempered strip and wire. In addition to their spring applications, these steels are used for such items as piano wire and saw blades. Quenched and tempered, high-carbon steels approach tensile strengths of 1378 MPa.

Free-machining carbon steels are low-carbon and medium-carbon grades with additions usually of sulfur (0.08%–0.13%), S–P combinations, and/or lead to improve machinability. They are AISI 1108–1151 for sulfur grades, and AISI 1211–1215 for phosphorus and sulfur grades. The latter may also contain bismuth and be lead free. The presence of relatively large amounts of sulfur and phosphorus can reduce ductility, cold formability, forgeability, weldability, as well as toughness and fatigue strength. Calcium deoxidized steels (carbon and alloy) have good machinability, and are used for carburized or through-hardened gears, worms, and pinions.

Low-temperature carbon steels have been developed chiefly for use in low-temperature equipment and especially for welded pressure vessels. They are low-carbon to medium-carbon (0.20%–0.30%), high-manganese (0.70%–1.60%), silicon (0.15%–0.60%) steels, which have a fine-grain structure with uniform carbide dispersion. They feature moderate strength with toughness down to –46°C.

For grain refinement and to improve formability and weldability, carbon steels may contain 0.01%–0.04% columbium. Called columbium steels, they are used for shafts, forgings, gears, machine parts, and dies and gauges. Up to 0.15% sulfur, or 0.045% phosphorus, makes them free-machining, but reduces strength.

Rail steel, for railway rails, is characterized by an increase of carbon with the weight of the rail. Railway engineering standards call for 0.50%–0.63% carbon and 0.60% manganese in a 27 kg rail, and 0.69%–0.82% carbon and 0.70%–1.0% manganese in a 64 kg rail. Rail steels are produced under rigid control conditions from deoxidized steels, with phosphorus kept below 0.04%, and silicon 0.10%–0.23%. Guaranteed minimum tensile strength of 551 MPa is specified, but it is usually much higher.

Sometimes, a machinery steel may be required with a small amount of alloying element to give a particular characteristic and

still not be marketed as an alloy steel, although trade names are usually applied to such steels. Superplastic steels, developed at Stanford University, with 1.3%–1.9% carbon, fall between high-carbon steels and cast irons. They have elongations approaching 500% at warm working temperatures of 538°C–650°C, and 4%–15% elongation at room temperature. Tensile strengths range from 1034 to over 1378 MPa. The extra-high ductility is a result of a fine, equiaxed grain structure obtained by special thermomechanical processing.

Damascus steels are 1%–2% carbon steels used for ancient swords made by blacksmiths using hot and warm forging, which developed layered patterns. The swords were eminent for their strength and sharp cutting edge. With carbon in the form of iron carbide, the forged products were free of surface markings. With carbon in the form of spherical carbide, the products could exhibit surface markings. So-called *welded Damascus steels*, also referred to as *pattern welded steels*, also exhibit surface markings. Superplasticity may be inherent in all of these steels.

Production Types

Steelmaking processes and methods used to produce mill products, such as plate, sheet, and bars, have an important effect on the properties and characteristics of the steel.

Deoxidation Practice

Steels are often identified in terms of the degree of deoxidation resulting during steel production. Killed steels, because they are strongly deoxidized, are characterized by high composition and property uniformity. They are used for forging, carburizing, and heat-treating applications. Semikilled steels have variable degrees of uniformity, intermediate between those of killed and rimmed steels. They are used for plate, structural sections, and galvanized sheets and strip. Rimmed steels are deoxidized only slightly during solidification. Carbon is highest at the center of the ingot. Because the outer layer of the ingot is relatively ductile, these steels are ideal for rolling. Sheet and strip made from rimmed steels have excellent surface quality and cold-forming characteristics. Capped steels have a thin low-carbon rim, which gives them surface qualities similar to rimmed steels. Their cross section uniformity approaches that of semikilled steels.

Melting Practice

Steels are also classified as air melted, vacuum melted, or vacuum degassed. Air-melted steels are produced by conventional melting methods, such as open hearth, basic O₂, and electric furnace. Vacuum-melted steels encompass those produced by induction vacuum melting and consumable electrode vacuum melting. Vacuum-degassed steels are air-melted steels that are vacuum processed before solidification. Compared with air-melted steels, those produced by vacuum-melting processes have lower gas content, fewer nonmetallic inclusions, and less center porosity and segregation. They are more costly, but have better mechanical properties, such as ductility and impact and fatigue strengths.

Rolling Practice

Steel mill products are produced from various primary forms such as heated blooms, billets, and slabs. These primary forms are first reduced to finished or semi-finished shape by hot-working operations. If the final shape is produced by hot-working processes, the steel is known as hot rolled. If it is finally shaped cold, the steel is known as cold finished, or more specifically as cold rolled or cold drawn. Hot-rolled mill products are usually limited to low and

medium, non-heat-treated, carbon steel grades. They are the most economical steels, have good formability and weldability, and are used widely for large structural shapes. Cold-finish shapes, compared with hot-rolled products, have higher strength and hardness and better surface finish, but are lower in ductility.

Carbon Tetrachloride

A heavy, colorless liquid of composition CCl_4 , tetrachloromethane, which is one of a group of chlorinated hydrocarbons. It is an important solvent for fats, asphalt, rubber, bitumens, and gums. It is more expensive than the aromatic solvents, but it is notable as a nonflammable solvent for many materials sold in solution and is widely used as a degreasing and cleaning agent in the dry-cleaning and textile industries. Since the *fumes* are highly toxic, it is no longer permitted in compounds for home use. It is used as a chemical in fire extinguishers such as Pyrene; but when it falls on hot metal, it forms a poisonous gas phosgene. It is also used as a disinfectant, and because of its high dielectric strength has been employed in transformers. Carbon tetrachloride is obtained by the chlorination of carbon disulfide. The specific gravity is 1.595, boiling point 169°F (76°C), and the freezing point 73°F (23°C). Chlorobromomethane, $\text{Br} \cdot \text{CH}_2 \cdot \text{Cl}$, is also used in fire extinguishers, as it is less corrosive and more than twice as efficient as an extinguisher. It is a colorless, heavy liquid with a sweet odor, a specific gravity 1.925, boiling point 153°F (67°C), and a freezing point -85°F (-65°C). It is also used as the high-gravity flotation agent.

Carbon Tube Furnace

An electric furnace that has a carbon retort for a resistor element and is especially suitable for the batch or continuous sintering of carbon-insensitive materials such as cement and carbides.

Carbonaceous

A material that contains carbon in any or all of its several allotropic forms.

Carbon-Carbon Composites

Carbon-carbon composites (C-C) provide high-strength, light weight, and resistance to high temperature and corrosion for pistons in both stationary and mobile engines.

Advantages in using carbon-carbon for both gasoline and diesel engines include increased performance (higher power output and faster engine acceleration); higher temperature operation for improved fuel economy; reduced levels of air pollutant emissions; and reduced noise, vibration, and harshness (NVH) levels. These benefits also could provide lower operational costs and reduced environmental impact.

Another carbon-carbon originally developed for use as rocket nozzles is now a replacement for graphite, quartz, and ceramic furnace components used in Czochralski crystal pulling, a processing step in semiconductor manufacturing. The material has a high strength-to-weight ratio, maintains its strength and rigidity despite high temperatures, resists wear, and is relatively chemically inert. When used in Czochralski furnaces, the thermal properties of the material lead to a 10% reduction in energy use and a 50% cut in cooling times. Because of the purity of the material, chipmakers achieve a 7% increase in wafer yields compared to furnaces with graphite components. See *composite materials*.

Carbonitriding

A *case hardening* process in which a suitable ferrous material is heated above the lower transformation temperature in a gaseous atmosphere of such composition as to cause simultaneous absorption of carbon and nitrogen by the surface and, by diffusion, create a concentration gradient. The heat-treating process is completed by cooling at a rate that produces the desired properties and the work-piece. See *case hardening*.

Carbonium Ion

Positively charged organic compound (ion).

Carbonization

The conversion of an organic substance into elemental carbon in an inert atmosphere at temperatures ranging from 800°C to 1600°C (1470°F to 2910°F) and higher, but usually at about 1315°C (2400°F). Range is influenced by precursor, processing of the individual manufacturer, and properties desired. Should not be confused with carburization.

Carbonizing Flame (in Gas Welding)

Same as carburizing flame. See preferred term *reducing flame*.

Carbonyl Powder

Metal powders prepared by the thermal decomposition of a metal carbonyl compound such as nickel tetracarbonyl $\text{Ni}(\text{CO})_4$ or iron pentacarbonyl $\text{Fe}(\text{CO})_5$. See also *thermal decomposition*.

Carbonyl Process

A process in which a metal carbonyl gas is heated to form a purified metal powder.

Carborundum

Silicon carbide, particularly as an abrasive.

Carburizing

(1) Absorption and diffusion of carbon into solid ferrous alloys by heating to a temperature usually above A_{c3} , in contact with a suitable carbonaceous material. A form of *case hardening* that produces a carbon gradient extending inward from the surface, enabling the surface layer to be hardened either by quenching directly from the carburizing temperature or by cooling to room temperature, then re-austenitizing and quenching. (2) The process by which carbon diffuses into the steel. The process can be deliberately induced by appropriate treatments. It can occur accidentally during some manufacturing processes with potentially adverse consequences for the component.

Carburizing Flame

A gas flame that will introduce carbon into some heated metals, as during a gas welding operation. A carburizing flame is a *reducing flame*, but a reducing flame is not necessarily a carburizing flame. Carburizing flames have a long feathery inner cone and a relatively low temperature.

Carburizing Secondary-Hardening Steels

Case-carburized steels subsequently hardened and strengthened by precipitation of M_2C carbide. Three steels developed by QuesTek Innovations LLC, include *Ferrium C862 stainless steel*, *GearMet C61%*, and *GearMet C69%* for gears and bearings. Ferrium C862 nominally contains 15% cobalt, 9.0% chromium, 1.5% nickel, 0.2% vanadium, 0.08% core carbon, balance iron. It is targeted at matching the surface properties of standard nonstainless gear steels, maintaining sufficient core strength and toughness, and having better corrosion resistance than 440C stainless steel. Core hardness is 50 Rockwell C, core toughness 1740 MPa mm^{1/2}, and surface hardness 62 Rockwell C. GearMet C61% has 18 cobalt, 9.5 nickel, 3.5 chromium, 1.1 molybdenum, 0.16 core carbon, balance iron. It is designed to provide surface properties similar to conventional gear steels and an ultrahigh strength core with superior fracture toughness. Core hardness is 54 Rockwell C, core toughness of more than 2610 MPa mm^{1/2}, and surface hardness 61 Rockwell C. GearMet C69% has 27.8–28.2 cobalt, 5–5.2 chromium, 2.9–3.1 nickel, 2.4–2.6 molybdenum, 0.09–0.11 core carbon, 0.015–0.025 vanadium, balance iron. It combines a tough ductile core with an ultrahard case. Core hardness is 50 Rockwell C and surface hardness 69 Rockwell C.

Carrier

In emission spectra chemical analysis, a material added to a sample to facilitate its controlled vaporization into the analytical gap. See also *analytical gap*.

Carrier Gas

In thermal spraying, the gas is used to carry the powdered materials from the powder feeder or hopper to the gun.

Cartridge Brass

Basically, a 70% copper, 30% zinc wrought alloy, designated *brass alloy C26000*, which may also contain as much as 0.07% lead and 0.05% iron. Besides cartridge brass, a name resulting from its use in munitions, notably cartridge cases, it has been known as *brass alloy 70–30 brass*, *spinning brass*, *spring brass*, and *extraquality brass*. Besides flat products, the alloy is available in bar, rod, wire, tubing, and, for cartridge cases, cups. It has excellent cold-forming characteristics and a machinability about 30% that of free-cutting brass. It is also relatively brazed and soldered and can be welded by oxyfuel and resistance methods. Its weldability by gas-metal-arc methods, however, is limited, and other welding methods are not advisable. Although corrosion-resistant in various waters and chemical solutions, the alloy may be susceptible to dezincification in stagnant or slow-moving, brackish waters and salt or slightly acidic solutions. Also, it is prone to stress-corrosion cracking, particularly in ammonia environments. Besides the additional applications, it is used for various stamped, spun, or drawn shapes, including lamp fixtures, shells and reflectors, autoradiator cores, locks, springs, fasteners, cylinder components, plumbing fixtures, and architectural grille work.

Cascade Separator

A special device to separate metal powder fractions of different particle size or specific gravity.

Cascade Sequence

A welding sequence in which a continuous multiple-pass weld is built up by depositing weld beads in overlapping layers, usually laid in a *back step sequence*. Compare with *block sequence*.

Case

In heat treating, that portion of the ferrous alloy, extending inward from the surface, whose composition has been altered during *case hardening*. Typically considered to be a portion of an alloy (a) whose composition has been measurably altered from the original composition, (b) that appears light when etched, or (c) that has a higher hardness value than the core. Contrast with *core*.

Case Crushing

A term used to denote longitudinal gouges arising from fracture in case-hardened gears.

Case-Hardening Materials

Case-hardening materials are those for adding carbon or other elements to the surface of low-carbon or medium-carbon steels or to iron so that upon quenching a hardened case is obtained, the center of the steel remaining soft and ductile. The material may be plain charcoal, raw bone, or mixtures marketed as carburizing compounds. A common mixture is about 60% charcoal and 40% barium carbonate. The latter decomposes, yielding CO₂, which is reduced to CO in contact with the hot charcoal. If charcoal is used alone, the action is slow and spotty. Coal or coke can be used, but the action is slow, and the sulfur in these materials is detrimental. Salt is sometimes added to aid the carburizing action. By proper selection of the carburizing material, the carbon content may be varied in the steel from 0.80% to 1.20%. The carburizing temperature for carbon steels typically ranges from 850°C to 950°C but maybe as low as 790°C or as high as 1095°C. The articles to be carburized for case hardening are packed in metallic boxes for heating in a furnace, and the process is called pack hardening, as distinct from the older method of burying the red-hot metal in charcoal.

Steels are also case-hardened by the diffusion of carbon and N₂, called carbonitriding, or N₂ alone, called nitriding. Carbonitriding, also known as dry cyaniding, gas cyaniding, liquid cyaniding, nitrating, and nitrocarburizing, involves the diffusion of carbon and N₂ into the case. Nitriding also may be done by gas or liquid methods. In carbonitriding, the steel may be exposed to a carrier gas containing carbon and as much as 10% ammonia (NH₃), the N₂ source, or a molten cyanide salt, which provides both elements. NH₃, from gaseous or liquid salts, is also the N₂ source for nitriding. Although low- and medium-carbon steels are commonly used for carburizing and carbonitriding, nitriding is usually applied only to alloy steels containing nitride-forming elements, such as aluminum, chromium, molybdenum, or vanadium. In ion nitriding, or glow-discharge nitriding, electric current is used to ionize low-pressure N₂ gas. The ions are accelerated to the workpiece by the electric potential, and the workpiece is heated by the impinging ions, obviating an additional heat source. Of the three principal case-hardening methods, all provide a hard wear-resistant case. Carburizing, however, which gives the greater case depth, provides the best contact-load capacity. Nitriding provides the best dimensional control and carbonitriding is intermediate in this respect.

The principal liquid-carburizing material is sodium cyanide, which is melted in a pot that the articles are dipped in, or the cyanide is rubbed on the hot steel. Cyanide hardening gives an extremely hard but superficial case. N_2 as well as carbon is added to the steel by this process. Gases rich in carbon, such as methane, may also be used for carburizing, bypassing the gas through the box in the furnace. When NH_3 gas is used to impart N_2 to the steel, the process is not called carburizing but is referred to as nitriding.

Chromized steel is steel surface-alloyed with chromium by diffusion from a chromium salt at high temperature. The reaction of the salt produces an alloyed surface containing about 40% chromium.

Metallizing is a diffusion coating process involving an electrolytic technique similar to electroplating, but done at higher temperatures (816°C–1093°C). The process uses a molten fluoride salt bath to diffuse metals and metalloids into the surface of other metals and alloys. As many as 25 different metals have been used as diffusing metals, and more than 40 as substrates. For example, boride coatings are applied to steels, nickel-base alloys, and refractory metals. Beryllide coatings can also be applied to many different metals by this process. The coatings are pore-free and can be controlled to a tolerance of 0.025 mm.

Casein

A whitish to yellowish, granular or lumpy protein precipitated from skim milk by the action of a dilute acid, or coagulated by rennet, or precipitated with whey from a previous batch. The precipitated material is then filtered and dried. Cow's milk contains about 3% casein. It is insoluble in water and alcohol, but soluble in alkalis. Although the casein is usually removed from commercial milk, it is a valuable food accessory because it contains *methionine*, a complex mercaptobutyric acid which counteracts a tendency toward calcium hardening of the arteries. This acid is also found in the ovalbumin of egg white. Methionine, $CH_3 \cdot S \cdot CH_2CH_2CHNH \cdot COOH$, is one of the most useful of the amino acids, and it is used in medicine to cure protein deficiency and in dermatology to cure acne and falling hair. It converts dietary protein to tissue, maintains nitrogen balance, and speeds wound healing. It is now made synthetically for use in poultry feeds. Some casein is produced as a by-product in the production of lactic acid from whole milk, the casein precipitating at a pH of 4.5. It is treated with sodium hydroxide to yield *sodium caseinate*.

Most of the production of casein is by acid precipitation, and this casein has a moisture content of not more than 10% with no more than 2.25% fat and not over 4% ash. The casein made with rennet is the type used for making plastics. *Rennet* used for curdling cheese is an extract of an enzyme derived from the stomachs of calves and lambs and is closely related to pepsin. Rennet substitutes produced from pepsin and other vegetable sources are only partial replacements and often have undesirable off-flavors. *Whey* is a thin, sweet, watery part separated out when milk is coagulated with rennet. Whey solids are used in prepared meats and other foods to enhance flavor and in pastries to eliminate sogginess. *Tekniken* is a dry whey for use in margarine, chocolate, and cheese. *Orotic acid*, produced synthetically, is identical with the biotic *Lactobacillus bulgaricus* of yogurt, the fermented milk whey used as food. It is a vitamin-like material.

Argentina and the United States are the most important producers of casein. France, Norway, and the Netherlands are also large producers. Casein is employed for making plastics, adhesives, sizing for paper and textiles, washable interior paints, leather dressings, and as a diabetic food. *Casein glue* is a cold-worked, water-resistant paste

made from casein by dispersion with a mild base such as ammonia. With a lime base it is more resistant but has a tendency to stain. It is marketed wet or dry, the dry powder being simply mixed with water for application. It is used largely for low-cost plywoods and in water paints, but it is not waterproof. Many gypsum wallboard cements are fortified with casein. Concentrated *milk protein*, available as *calcium caseinate* or *sodium caseinate*, is for adding proteins and for stabilizing prepared meats and bakery products. It contains eight amino acids and is high in lysine. *Sheftene* is this material.

Casein Adhesive

An aqueous colloidal dispersion of *casein* that may be prepared with or without heat that may contain modifiers, inhibitors, and secondary binders to provide specific adhesive properties; and that includes a subclass, usually identified as casein glue, that is based on a dry blend of casein, lime, and sodium salts, mixed with water prepared without heat.

Casein Plastics

A group of thermoplastic molding materials made usually by the action of formaldehyde on rennet casein. The process was invented in 1885, and the first commercial casein plastic was called *Galalith*, meaning *milk stone*. Casein plastics are easily molded, machine easily, are nonflammable, withstand temperatures up to 300°F (150°C) and are easily dyed to light shades. But they are soft, have a high water absorption (7%–14%), and so often when exposed to alkalis. They are thus not suitable for many mechanical or electrical parts. They are used for ornamental parts, buttons, and such articles as fountain-pen holders. *Casein fiber* is made by treating casein with chemicals to extract the albumen and salts, forcing it through spinners, and again treating it to make it soft and silk-like. The fiber is superior to wool in silkiness and resistant to moth attack, but is inferior in general properties. It is blended with wool and fabrics and in hat felts.

CASS Test

Abbreviation for *copper-accelerated salt-spray test*.

Cassette

A holder used to contain radiographic film storing exposure to x-rays or gamma rays, that may or may not contain intensifying or filter screens, or both. A distinction is often made between a cassette, which is a positive means for ensuring contact between screens and film and is usually rigid, and an exposure holder, which is rather flexible.

Cast

- (1) The practice of pouring molten metal into a mold and allowing it to solidify. If the resultant item is of approximately the final shape, requiring only final machining and other treatments that do not involve significant deformation, it will be described as a casting. If the cast item is to be wrought to shape by rolling, forging, etc., it will usually be described as an ingot. See also *continuous casting*.
- (2) The natural curved form that a wire takes as it is drawn from a reel and allowed to lie unrestrained. Its measure is the diameter of the circle formed when a sufficiently is allowed to lie freely on a horizontal surface.

Cast (Plastics)

To form a “plastic” object by pouring a fluid monomer–polymer solution into an open mold where it finishes polymerizing. Forming plastic film and sheet by pouring the liquid resin onto a moving belt or by precipitation in a chemical bath.

Cast Corrosion-Resistant Stainless Steels

High chromium-containing (11%–30% Cr) cast steels have been specified for liquid corrosion service at temperatures below 650°C (1200°F). Corrosion-resistant, or C-type steel castings are classified on the basis of composition using the designation system of the High Alloy Product Group of the Steel Founder’s Society of America. The first letter of the designation (C) indicates that the alloy is intended for liquid corrosion service. The second letter indicates the nickel content; as the nickel content increases, the second letter of the designation changes from A to Z.

Cast Film

A film made by depositing a layer of liquid plastic onto a surface and stabilizing this form by the evaporation of solvent, by fusing after deposition, or by allowing a melt to cool. Cast films are usually made from solutions or dispersions.

Cast Heat-Resistant Stainless Steels

Iron–chromium, iron–chromium–nickel, and iron–nickel–chromium steel castings have been specified for service at temperatures 650°C (1200°F) to approximately 980°C (1800°F). Designated similarly to *cast corrosion-resistant stainless steels*, H-type steels (the “H” denoting high-temperature service) have nickel contents ranging from 0% to 68%.

Cast Iron

Alloys of iron containing, at the time they are cast, carbon in the range from about 2% to 4%. This contrasts with steel which is also an iron carbon alloy but which contains considerably less carbon. It is common for the term “cast” to be omitted in description such as “Grey (cast) Iron,” “Malleable (cast) Iron” or even “(cast) Irons.” Iron containing about 3% carbon solidifies over a temperature range from about 1350°C to 1130°C, i.e., significantly lower than the 1535°C or so melting point of pure iron. This wide freezing range coupled with a high fluidity ensures that complex shapes are readily cast. Other favorable characteristics of the simple irons include good corrosion resistance (relative to carbon steel) and erosion resistance, a high damping capacity and good compressive strength. Cast irons can develop, under appropriate cooling conditions and by subsequent heat treatment, like

the structures for steel. However, the very high carbon content has a significant effect and, in the as-cast condition, the structure will contain either soft, weak, free carbon, that is, carbon not combined with the iron, or large quantities of hard, brittle cementite (iron carbide). Factors such as precise composition and cooling rate during casting influence structures that initially develop. In many irons, the free carbon will exist as graphite flakes. This usually forms as a eutectic with the austenite at 1130°C but in adverse circumstances a coarse form, termed *Kish graphite*, can be precipitated at an earlier stage of solidification. However, even normal graphite flakes have a pronounced weakening effect although some improvement can be obtained by inoculation which involves adding a finely particulate refractory powder, such as calcium silicide, to the molten iron. The particles provide a larger number of nucleation sites for precipitation thereby refining the graphite. When irons containing graphite flakes are broken the fracture follows the weak flakes producing a characteristic grey fracture surface. Historically, irons have been categorized on the appearance of their fracture surface and hence such irons are termed *Grey Irons*. Apart from the graphite the microstructure will comprise a matrix of other phases such as pearlite or ferrite hence terms such as *Pearlitic Grey Iron* and *Ferritic Grey Iron*. Where the composition and cooling rate are such that no graphite is formed and the structure comprises cementite and pearlite the material will be very hard and brittle with a bright fracture surface, hence the term *White Iron*. The mechanical properties, particularly ductility and malleability, of white irons can be improved by various heat treatments to form *Malleable Irons*. Heating a white iron at about 850°C–950°C in a nonreactive environment for a long period (up to a week) causes the cementite to decompose producing a microstructure of ferrite with temper carbon, i.e., graphite in a nodular or rosette form which is not so damaging as flake. These carbon nodules are more prolific toward the center of this section so the appearance of the fracture surface leads to the term *Blackheart (Malleable) Iron*. A variation on this process requires a second heating to 900°C allowing some of the carbon to redissolve in the austenite so that pearlite is produced on cooling, hence the term *Pearlitic Malleable Iron*. Such irons can be heat-treated just like steel. An alternative malleablizing treatment involves heating white iron at about 950°C in an oxidizing environment for up to 100 h during which most of the carbon diffuses to the surface to react with oxygen-forming carbon dioxide. The resulting structure is largely ferritic or pearlitic, with a little temper carbon at the center (more in large castings), hence the name *Whiteheart (Malleable) Iron*. An alternative approach to producing more ductile irons is to modify the form of the graphite in the as-cast state, usually by small additions of magnesium or cerium to the molten iron. These promote the formation of graphite in the nodular or spheroidal form which, compared with the flake form, has only a slightly adverse effect on the mechanical properties. These materials are referred to as *Ductile Irons*, *Nodular Irons*, *Spheroidal Graphite Irons (SG Irons)*. See Tables C.4 and C.5.

TABLE C.4
Range of Compositions for Typical Unalloyed Common Cast Irons

Type of Iron	Composition, %				
	C	Si	Mn	P	S
Gray (FG)	2.5–4.0	1.0–3.0	0.2–1.0	0.002–1.0	0.02–0.25
Compacted graphite (CG)	2.5–4.0	1.0–3.0	0.2–1.0	0.01–0.1	0.01–0.03
Ductile (SG)	3.0–4.0	1.8–2.8	0.1–1.0	0.01–0.1	0.01–0.03
White	1.8–3.6	0.5–1.9	0.25–0.8	0.06–0.2	0.06–0.2
Malleable (TG)	2.2–2.9	0.9–1.9	0.15–1.2	0.02–0.2	0.02–0.2

TABLE C.5
Classification of Cast Iron by Commercial Designation, Microstructure, and Fracture

Commercial Designation	Carbon-Rich Phase	Matrix ^a	Fracture	Final Structure After
Gray iron	Lamellar graphite	P	Gray	Solidification
Ductile iron	Spheroidal graphite	F, P, A	Silver-gray	Solidification or heat treatment
Compacted graphite iron	Compacted vermicular graphite	F, P	Gray	Solidification
White iron	Fe ₃ C	P, M	White	Solidification and heat treatment ^b
Mottled iron	Lamellar Gr + Fe ₃ C	P	Mottled	Solidification
Malleable iron	Temper graphite	F, P	Silver-gray	Heat treatment
Austempered ductile iron	Spheroidal graphite	At	Silver-gray	Heat treatment

^a F, ferrite; P, pearlite; A, austenite; M, martensite; At, austempered (bainite).

^b White irons are not usually heat treated, except for stress relief and to continue austenite transformation.

In some cases, iron microstructure may be all ferrite—the same constituent that makes low-carbon steels soft and easily machined. But the ferrite of iron is different because it contains sufficient dissolved silicon to eliminate the characteristic gummy nature of low-carbon steel. Thus, cast irons containing ferrite do not require sulfur or lead additions in order to be free machining.

Because the size and shape of a casting control its solidification rate and strength, design of the casting and the casting process involved must be considered in selecting the type of iron to be specified. Although most other metals are specified by a standard chemical analysis, a single analysis of cast iron can produce several entirely different types of iron, depending upon foundry practice and shape and size of the casting, all of which influence cooling rate. Thus, iron is usually specified by mechanical properties. For applications involving high temperatures or requiring specific corrosion resistance, however, some analysis requirements may also be specified.

Pattern making is no longer a necessary step in manufacturing cast iron parts. Many gray, ductile, and alloy-iron components can be machined directly from bar that is continuously cast to near-net shape. Not only does this “parts-without-patterns” method save the time and expense of pattern making, continuous cast iron also provides a uniformly dense, finer-grained structure, essentially free from porosity, sand, or other inclusions. Keys to the uniform microstructure of the metal are the ferrostatic pressure and the temperature-controlled solidification that are unique to the process.

For each basic type of cast iron, there are a number of grades with widely differing chemical properties. These variations are caused by differences in the microstructure of the metal that surrounds the graphite (or iron carbides). Two different structures can exist in the same casting. The microstructure of cast iron can be controlled by heat treatment, but once graphite is formed, it remains.

Pearlitic cast iron grades consist of alternating layers of soft ferrite and hard iron carbide. This laminated structure—called pearlite—is strong and wear resistant, but still quite machinable. As laminations become finer, hardness and strength of the iron increase. Laminations size can be controlled by heat treatment or cooling rate.

Cast irons that are flame-hardened, induction-hardened, or furnace-heated and subsequently oil-quenched contain a martensite structure. When tempered, this structure provides machinability with maximum strengths and good wear resistance.

Gray Iron

This is a supersaturated solution of carbon in an iron matrix. The excess carbon precipitates out in the form of graphite flakes.

Gray iron is specified by a two-digit designation; Class 20, for example, specifies a minimum tensile strength of 138 MPa. In addition, gray iron is specified by the cross section and minimum strength of a special test bar. Usually, the test bar cross section matches or is related to a particularly critical section of the casting. This second specification is necessary because the strength of gray iron is highly sensitive to cross section (the smaller the cross section, the faster the cooling rate and the higher the strength).

Impact strength of gray iron is lower than that of most other cast ferrous metals. In addition, gray iron does not have a distinct yield point (as defined by classical formulas) and should not be used when permanent, plastic deformation is preferred to fracture. Another important characteristic of gray iron—particularly for precision machinery—is its ability to damp vibration. Damping capacity is determined principally by the amount and type of graphite flakes. As graphite decreases, damping capacity also decreases.

The high compressive strength of gray iron—three to five times tensile strength—can be used to advantage in certain situations. For example, placing ribs on the compression side of a plate instead of the tension side produces a stronger, lighter component.

Gray irons have excellent wear resistance. Even the softer grades perform well under certain borderline lubrication conditions (as in the upper cylinder walls of internal-combustion engines, for example).

To increase the hardness of gray iron for abrasive-wear applications, alloying elements can be added, special foundry techniques can be used, or the iron can be heat-treated. Gray iron can be hardened by flame or induction methods, or the foundry can use a chill in the mold to produce hardened, “white-iron” surfaces.

Typical applications of gray iron include automotive engine blocks, gears, flywheels, brake disks and drums, and machine bases. Gray iron serves well in machinery applications because of its good fatigue resistance.

Ductile Iron

Ductile, or nodular iron, contains trace amounts of magnesium which, by reacting with the sulfur and oxygen in the molten iron, precipitates out carbon in the form of small spheres. These spheres improve the stiffness, strength, and shock resistance of ductile iron over gray iron. Different grades are produced by controlling the matrix structure around the graphite, either as-cast or by subsequent heat treatment.

A three-part designation system is used to specify ductile iron. The designation of a typical alloy, 60-40-18, for example, specifies a minimum tensile strength of 414 MPa, a minimum yield strength of 276 MPa, and 18% elongation in 5.08 mm.

Ductile iron is used in applications such as crankshafts because of its good machinability, fatigue strength, and high modulus of elasticity; in heavy-duty gears because of its high yield strength and wear resistance; and in automobile door hinges because of its ductility. Because it contains magnesium as an additional alloying element, ductile iron is stronger and more shock resistant than gray iron. But although ductile iron also has a higher modulus of elasticity, its damping capacity and thermal conductivity are lower than those of gray iron.

By weight, ductile iron castings are more expensive than gray iron. Because they offer higher strength and provide better impact resistance, however, overall part costs may be about the same.

Although it is not a new treatment for ductile iron, austempering has become increasingly known to the engineering community in the past 5–10 years. Austempering does not produce the same type of structure as it does in steel because of the high carbon and silicon content of iron. The matrix structure of austempered ductile iron (ADI) sets it apart from other cast irons, making it truly a separate class of engineering materials.

In terms of properties, the ADI matrix almost doubles the strength of conventional ductile iron while retaining its excellent toughness. Like ductile iron, ADI is not a single material; rather, it is a family of materials having various combinations of strength, toughness, and wear resistance. Unfortunately, the absence of a standard specification for the materials has restricted its widespread acceptance and use. To help eliminate this problem, the Ductile Iron Society has proposed property specifications for four grades of austempered ductile iron.

Most current applications for ADI are in transportation equipment—automobiles, trucks, and railroad and military vehicles. The same improved performance and cost savings are expected to make these materials attractive in equipment for other industries such as mining, earthmoving, agriculture, construction, and machine tools.

White Iron

White iron is produced by “chilling” selected areas of a casting in the mold, which prevents graphitic carbon from precipitating out. Both gray and ductile iron can be chilled to produce a surface of white iron, consisting of iron carbide, or cementite, which is hard and brittle. In castings that are white iron throughout, however, the composition of iron is selected according to part size to ensure that the volume of metal involved can solidify rapidly enough to produce the white-iron structure.

The principal disadvantage of white iron is its brittleness. This can be reduced somewhat by reducing the carbon content or by thoroughly stress-relieving the casting to spheroidize the carbides in the matrix. However, these measures increase cost and reduce hardness.

Chilling should not be confused with heat-treat hardening, which involves an entirely different metallurgical mechanism. White iron, so-called because of its very white structure, can be formed only by solidification. It will not soften except by extended annealing and it retains its hardness even above 538°C.

White irons are used primarily for applications requiring wear and abrasion resistance such as mill liners and shot-blasting nozzles. Other uses include railroad brake shoes, rolling-mill rolls, clay-mixing and brickmaking equipment, and crushers and pulverizers. Generally, plain (unalloyed) white iron costs less than other cast irons.

Compacted Graphite Iron

Until recently, compacted graphite iron (CGI), also known as vermicular iron, has been primarily a laboratory curiosity. Long known as an

intermediate between gray and ductile iron, it possesses many of the favorable properties of each. However, because of process-control difficulties and the necessity of keeping alloy additions within very tight limits, CGI has been extremely difficult to produce successfully on a commercial scale. For example, if the magnesium addition varied by as little as 0.005%, results would be unsatisfactory.

Processing problems have been solved by an alloy-addition package that provides the essential alloying ingredients—magnesium, titanium, and rare earths—in exactly the right proportions.

Strength of CGI parts approaches that of ductile cast iron. CGI also offers high thermal conductivity, and its damping capacity is almost as good as that of gray iron; fatigue resistance and ductility are similar to those properties in ductile iron. Machinability is superior to that of ductile iron, and casting yields are high because shrinkage and feeding characteristics are more like gray iron.

The combination of high strength and high thermal conductivity suggests the use of CGI in engine blocks, brake drums, and exhaust manifolds of vehicles. CGI gear plates have replaced aluminum in high-pressure gear pumps because of the ability of the iron to maintain dimensional stability at pressures above 10.3 MPa.

Malleable Iron

Malleable iron castings are often used for heavy-duty bearing surfaces in automobiles, trucks, railroad rolling stock, and farm and construction machinery. Pearlitic grades are highly wear resistant, with hardnesses ranging from 152 to over 300 Bhn. Applications are limited, however, to relatively thin-sectioned castings because of the high shrinkage rate and the need for rapid cooling to produce white iron.

High-Alloy Irons

High alloy-irons are ductile, gray, or white irons that contain 3% to more than 30% alloy content. Properties are significantly different from those of unalloyed irons. These irons are usually specified by chemical composition as well as by various mechanical properties.

White high-alloy irons containing nickel and chromium develop a microstructure with a martensite matrix around primary chromium carbides. This structure provides a high hardness with extreme wear and abrasion resistance. High-chromium irons (typically, about 16%) combine wear and oxidation resistance with toughness. Irons containing from 14% to 24% nickel are austenitic; they provide excellent corrosion resistance for nonmagnetic applications. The 35% nickel irons have an extremely low coefficient of thermal expansion and are also nonmagnetic and corrosion resistant.

Cast Nonferrous Alloys

Nonferrous metals and alloys can be categorized as follows:

1. Aluminum-base
2. Copper-base (brasses and bronzes)
3. Lead-base
4. Magnesium-base
5. Nickel-base
6. Tin-base
7. Zinc-base
8. Titanium-base

Another common way of grouping nonferrous alloys is to divide them into heavy metals (copper, zinc, lead, and nickel) and light metals (aluminum, magnesium, and titanium base).

Aluminum and Its Alloys

Aluminum and its alloys continue to grow in acceptance, particularly in the automotive industry. The electronics industry is another major user of cast aluminum for chassis, enclosures, terminals, etc.

Most metallic elements can be alloyed readily with aluminum, but only a few are commercially important—among them copper, lithium, magnesium, manganese, silicon, and zinc. Many other elements serve as supplementary alloying additions to improve properties and metallurgical characteristics.

Aluminum can be cast by virtually all of the common casting processes—particularly diecasting, sand mold, permanent mold, expendable pattern (lost foam) casting, etc.

Aluminum alloy castings are produced by virtually all commercial processes in a range of compositions possessing a wide variety of useful engineering properties.

- Al–Mg alloys offer excellent corrosion resistance, good machinability, and an attractive appearance when anodized. Careful gating and risering are required.
- Binary Al–Si alloys exhibit good weldability, high corrosion resistance, and low specific gravity.
- Al–Zn alloys have good machinability characteristics and age at room temperature to moderately high strengths in a relatively short period of time without solution heat treatment.
- Al–Sn alloys were developed for bearings and bushings with high load-carrying capacity and fatigue strength. Corrosion resistance is superior, but there is a susceptibility to hot cracking.
- Al–Li alloys are of recent commercial significance because of their good mechanical properties. They are believed to have many potential aerospace applications, and alloy development is widespread.

Copper Casting Alloys

These alloys are grouped according to composition by these general categories: pure copper, high-copper alloys, brasses, leaded brasses, bronzes, aluminum bronzes, silicon bronzes, Cu–Ni alloys, and Cu–Ni–Zn alloys known as “nickel silvers.” The UNS designations for copper-base casting alloys range from C80000 through C99900. In brasses, zinc is the principal alloying element. For cast brass, there are Cu–Zn–Sn alloys (red, semi-red, and yellow brasses), leaded and unleaded manganese bronze alloys (high-strength yellow brasses), and Cu–Zn–Si alloys.

Tin is the principal alloying element in cast bronze alloys, which consist of four families: tin bronzes, leaded and highly leaded tin bronzes, Ni–Sn bronzes, and aluminum bronzes.

Zinc Alloys

Zinc has a low melting temperature and is readily and economically diecast. In recent years, zinc “foundry alloys” known as the ZA-8, ZA-12, and ZA-27 (containing 8%, 12%, and 27% aluminum, respectively) have been developed. They are finding wide application as gravity-cast sand and permanent mold castings as well as diecastings.

Zinc alloys can be cast in thin sections and with tight dimensional control. The principal alloys used for diecastings contain low percentages of magnesium, 3.9%–4.3% aluminum, and small controlled quantities of impurities such as tin, lead, and cadmium. Copper, and nickel are significant alloying additions.

Magnesium Alloys

The usefulness of magnesium, lightest of the commercial metals, is enhanced considerably by alloying. Magnesium can be used for sand and permanent mold castings and diecastings. Hot-chamber diecasting is a more recent development that is finding wider application each year. With the help of different heat treatments, alloy tensile strengths range from 136 to 262 MPa, yield strengths from 69 to 262 MPa, and elongations from 1% to 15%.

Magnesium foundry technology has advanced significantly in recent years. Complex components are successfully made as sand castings, with wall thicknesses down to 3.5 mm and tolerances to ± 0.6 mm for automotive, aircraft, and electronics applications.

Titanium Castings

Applications are broadening. Titanium is particularly suitable for withstanding corrosive environments or applications that take advantage of its light weight, high strength-to-weight ratio, and nonmagnetic properties. Long applied in military aircraft, titanium alloys are now solving problems in nonmilitary equipment and jewelry.

Metal Matrix Composites (MMC)

MMCs are an important new technology. These compounds consist of an inorganic reinforcement-particle filament, or whisker, in a metal matrix. Nearly all metals can be used as a matrix, but current applications center around aluminum, magnesium, and titanium. The lighter metals offer the best weight-to-strength ratio. MMCs also show improved wear resistance and allow adjustment of the coefficient of thermal expansion to meet varying requirements.

Superalloys

Superalloys are nickel, Fe–Ni, and cobalt-base alloys generally used at temperatures above about 538°C. The Fe–Ni-base superalloys are an extension of stainless steel technology and generally are wrought, whereas cobalt-base and nickel-base superalloys can be wrought or cast.

The more highly alloyed compositions normally are processed as castings. Fabricated cast structures can be built up by welding or brazing, but many highly alloyed compositions containing a high amount of hardening phase are difficult to weld. Properties can be controlled by adjustments in composition and by processing including heat treatment.

Cast Plastics

Plastics casting materials can be generally classified in two groups: (1) those resins, usually thermosetting, that are cast as liquids and cured by chemical cross-linking either at room temperature or elevated temperatures, and (2) thermoplastics that are supplied essentially in suspension or monomeric form and fused or polymerized at elevated temperatures.

Materials

Each casting resin has a unique combination of properties, such as heat resistance, strength, electrical properties, chemical resistance, cost, and shrinkage, which dictate their use for specific applications.

The most commonly used casting resins are phenolics, polyesters, and epoxies. Others are phenolics, acrylics, and urethane elastomers. Following is a brief description of each major type.

Phenolic Resins

Phenolic resins are used for low-cost parts requiring good electrical insulating properties, heat resistance, or chemical resistance. The average shelf life of this resin is about 1 month at 21.1°C. This can be extended by storing it in a refrigerator at 1.6°C–10°C. Varying the catalyst (according to the thickness of the cast) and raising the cure temperature to 93°C will alter the cure time from as long as 8 h to as short as 15 min.

Some shrinkage occurs in the finished casting (0.012–0.6 mm/mm), depending on the quantity of filler, amount of catalyst, and the rate of cure. Faster cure cycles produce a higher rate of shrinkage. Since the cure cycle can be accelerated, phenolics are used in short-run casting operations.

Cast phenolic parts are easily removed from the mold if the parting agents recommended by the supplier are used. Postcuring improves the basic properties of the finished casting.

Polyester Resins

Polyester resins are primarily used in large castings such as those required in the motion picture industry or for large sculptures for museums, parks, and display purposes. Since polyester shrinkage is about 0.024–0.032 mm/mm, castings are usually reinforced with glass cloth or mat and are generally cast in a flexible mold. Catalysts used to initiate the cure are peroxides or hydroperoxides and activators are cobalt naphthanate, alkyl mereaptans, or dialkyl aromatic amines. Recently, isophthalic polyesters have been introduced containing isophthalic acid, which provides improved heat, chemical, and impact resistance.

Clear polyester castings can be made using diallyl or triallyl cyanurate type polyesters. Triallyl cyanurate polyesters are used in casting clear sheets because they have excellent scratch and heat resistance.

Acrylic Resins

The process involved in casting acrylic resins is complex and forms a specialized field. The methyl-methacrylate monomer contains inhibitors that must be removed before adding the catalyst. The resin must be cured under very accurately controlled conditions. The primary use of cast acrylics is in optically clear sheet, rod, or tube stock and in the embedment of specimens for museums and display of industrial parts, as well as for the embedment of decorative motifs in the jewelry industry.

Vinyls

Plasticized vinyls (polyvinyl chloride, or PVC) are used in industry in a variety of plastisol processing techniques, for example, slush casting and rotational casting. Electroformed molds are commonly used for this purpose. Since the conversion of the semiliquid vinyl plastisol to a solid consists of fusing the suspended vinyl particles to each other, it is only necessary to raise the temperature of the mass to 82°C–177°C according to the formulation. Cast-vinyl prototype parts can be produced that are comparable with molded parts.

Epoxy Resins

Most cast epoxy resins, other than those used in plastic tooling, are used in encapsulating electrical components and in casting prototype parts. The variations in properties possible make them very versatile materials. They can be made to have almost infinite shelf

life, can be varied from a liquid to a thixotropic gel, and can be highly flexibilized by the addition of polysulfides and polyamides. They can be formulated to provide heat resistance up to 260°C.

Cure cycles may range from 1 to 16 h, at which time the casting is removed from the mold. Epoxy resins for casting are available in transparent water-white, semitransparent, and opaque formulations. Room-temperature cures are effected when aliphatic amines are added to the resin in exact amounts. Heat resistance of such systems is about 82°C. Cure is relatively rapid; therefore, exothermic reaction produces relatively high temperatures. Thus, casting must generally be limited in thickness.

Proprietary amine hardeners and epoxy resin systems are available whose heat resistance is about 121°C–177°C. The use of liquid anhydrides yields castings with heat resistance above 204°C. Such systems permit casting in large masses because the exothermic reaction and the curing temperatures are low (about 121°C). The pot life is several days, because elevated temperatures are required to initiate the reaction.

Several facts are basic in the use of these systems. Because it is necessary to use acidic catalysts in order to achieve heat resistance, castings tend to be more brittle; also, more difficulty is encountered in releasing the cast from the mold. The use of the proper release agent with a given resin system is necessary to overcome this tendency.

Cast Replica

In *metallography*, a reproduction of a surface in plastic made by the evaporation of the solvent from a solution of the plastic or by polymerization of a monomer on the surface. See also *replica*.

Cast Steels

The general nature and characteristics of cast steels are, in most respects, closely comparable to wrought steels. Cast and wrought steels of equivalent composition respond similarly to heat treatment and have fairly similar properties. A major difference between them is that cast steel is more isotropic in structure. Therefore, properties tend to be more uniform in all directions in contrast to wrought steel, whose properties generally vary, depending on the direction of hot or cold working.

Five basic steel groups are available:

1. Carbon steels
2. Low-alloy steels
3. High-alloy steels
4. Tool steels
5. Stainless steels

The most common types of steels used in castings are the carbon steels, which contain only carbon as their principal alloying element. Other elements are present in small quantities, including those added for deoxidation. Silicon and manganese in cast carbon steels typically range from 0.25% to about 0.8% silicon and 0.50% to 1% manganese, respectively.

Cast plain carbon steels can be divided into three groups—low, medium, and high carbon. However, cast steel is usually specified by mechanical properties, primarily tensile strength, rather than composition. Standard classes are 414, 483, 586, and 690 MPa. Low-carbon grades, used mainly in the annealed and normalized conditions, have tensile strength ranging from 380 to 448 MPa. Medium-carbon grades, annealed and normalized, range from 483 to 690 MPa. When quenched and tempered, strength exceeds 690 MPa.

Ductility and impact properties of cast steels are comparable, on average, to those of wrought carbon steel. However, the longitudinal properties of rolled and forged steels are higher than those of cast steel. Endurance limit strength ranges between 40% and 50% of ultimate tensile strength.

By definition, low-alloy steels contain alloying elements, in addition to carbon, up to a total content of 8%. A casting containing more than 8% alloy content is classified as a high-alloy steel. Technically, tool steels and stainless steels are high-alloy steels but are normally classified separately.

Small quantities of titanium and aluminum are also used for grain refinement in cast low-alloy steels.

Stainless steels are grouped in three classes: martensitic, ferritic, and austenitic. They are all more resistant to corrosion than plain carbon steels or lower alloy steels, and they contain either significant amounts of chromium or chromium and nickel. Cast stainless steel grades are designated in general as either heat resistant or corrosion resistant. Stainless steel castings are specified by ACI designations.

The C series of ACI stainless grades designates corrosion-resistant steels; the H series designates heat-resistant steels that are suitable for service temperatures in the 649°C–1204°C range. Typical casting applications for C-series grades are valves, pumps, and fittings. H-series grades are used for furnace parts, turbine engine components, and other high-temperature requirements.

Interest has renewed in cast duplex stainless steels because the 50% ferritic and 50% austenitic metallographic structure of these grades makes them extremely resistant to stress corrosion cracking. In addition, they have twice the yield strength of austenitic grades and may cost less.

Although the basic properties of cast duplex alloys are determined primarily by the 50/50 mixture of ferrite and austenite, the metallurgy can be complex because of the numerous carbides, nitrides, and intermetallic phases or compounds that can form. Ferrite formation is a function of cooling rate and chemistry, and austenizing temperature affects strength.

Hardenability of cast steels does not vary significantly from that of wrought steels of similar composition. The one principal difference between wrought and cast steels is the effect of the casting surface. It may contain scale and oxides and may not be chemically or structurally equivalent to the base metal; see Table C.6.

A few of the industries and some of the specific products that are being made from cast steel are: automotive (frames, wheels, gears); electrical manufacturing (rotors, bases, housings, frames, shafts); transportation (couplings, drawbars, brake shoes, wheel truck frames); marine (rotors, sterns, anchor chains, ornamental fittings, capstans); off-the-road equipment (crawler side frames, levers, shafts, tread links, turntables, buckets, dipper teeth); municipal (fire hydrants, catch basins, manhole frames and covers); miscellaneous (ingot and pig molds, rolling mill rolls, blast-furnace ingot buggies, engine housings, cylinder blocks and heads, crankshafts, flanges and valves).

Cast Structure

The metallographic structure of a *casting* evidenced by shape and orientation of grains and by segregation of impurities. Other features include grains that are very coarse, possibly cored or dendritic, extensive columnar grains at the exterior and large quantities of internal voids.

Castability

(1) A complex combination of liquid-metal properties and solidification characteristics that promotes accurate and sound final castings.

(2) The relative ease with which a molten metal flows through a mold or casting die.

Castable

In casting, a combination of refractory grain and suitable bonding agent that, after the addition of a proper liquid, is generally poured into place to form a refractory shape or structure which becomes rigid because of chemical action.

Cast-Alloy Tool

A cutting tool made by casting a cobalt-based alloy and used at machining speeds between those for high-speed steels and cemented carbide. Nominal compositions for two commercially available grades are as follows in Table C.7.

Casting Copper

Fire-refined tough pitch copper usually cast from melted secondary metal into ingot bars only, and used for making foundry castings but not wrought products.

Casting Defect

Any imperfection in a casting that does not satisfy one or more of the required design or quality specifications. This term is often used in a limited sense for those flaws formed by improper casting solidification.

Casting Section Thickness

The wall thickness of the casting. Because the casting may not have a uniform thickness, the section thickness may be specified at a specific place on the casting. Also, it is sometimes useful to use the average, minimum, or typical wall thickness to describe the casting.

Casting Shrinkage

The amount of dimensional change per unit length of the casting as it solidifies in the mold or die and cools to room temperature after removal from the mold or die. There are three distinct types of casting shrinkage. Liquid shrinkage refers to the reduction in volume or liquid metal as it cools to the liquidus. Solidification shrinkage is the reduction in volume of metal from the beginning to the end of solidification. Solid shrinkage involves a reduction in volume of metal from the solidus to room temperature.

Casting Strains

Strains in a casting caused by *casting stresses* that develop as a casting cools.

Casting Stresses

Residual stresses set up when the shape of a casting impedes contraction of the solidified casting during cooling.

Casting Thickness

See *casting section thickness*.

Casting Volume

The total cubic units (mm³ or in.³) of cast metal in the casting.

Casting Yield

The weight of a casting(s) divided by the total weight of metal poured into the mold, expressed as a percentage.

Casting Wheel

A wheel carrying at its edge a number of molds which are filled as they pass beneath the molten metal stream. As the wheel rotates the molds are replaced or emptied if sufficiently cool.

Castings

Strength and performance of a cast part do not depend solely on part geometry. Proper alloy selection is crucial to a cost-effective casting design and trouble-free engineering and manufacturing. Materials

selection software has been developed to help meet the need for information about alloys. Because the packages are in a database format, users can search through the data to choose those materials that meet their requirements. Once the basic material selection has been made, three-dimensional (3-D) modeling, casting simulation, and finite-element analysis (FEA) software can be used to confirm the behavior of that material/part combination during manufacture and in service.

Rapid Prototyping

Computer technologies known as rapid prototyping allow manufacturers to fabricate 3-D models, prototypes, patterns, tooling, and production parts directly from computer-aided design (CAD) data in a fraction of the total time and cost of conventional methods. Several practical rapid prototyping systems are commercially available, and their use by OEM product parts designers as well as producers of cast metal parts and tooling shops are becoming widespread.

Each technology shares the same basic approach: A computer analyzes a 3-D CAD file that defines the object to be fabricated and “slices” the object into thin cross sections. The cross sections are then systematically recreated and combined to form a 3-D object.

Here’s a thumbnail sketch of how they work: Stereolithography recreates the object by sequentially solidifying layers of photoactive liquid polymer by exposing the liquid to ultraviolet light.

Ultimately, scientists hope to develop numerical simulations that provide enough information to optimize all the variables in a casting operation. To improve understanding of the process and to improve gating design, researchers use an x-ray system that makes images of the molten metal as it fills the mold. Computer codes that predict mechanical properties are then compared with experimental results and modified to match the behavior of specific alloys.

Metal-Casting Processes

Expendable molds are for use only once (sand castings); other molds (or dies) are made of metal (permanent molding and diecasting) and can be used repeatedly. The pattern must be removable from the mold without damage, and the casting must be removable from the mold or die without damage to either the die or the casting.

Sand Casting Processes

More than 80% of all castings made in the United States are produced by green sand molding. (The term *green sand* does not refer

to color, but to the fact that a raw sand and binder mixture has been tempered with water.) Sand molding is a versatile metal-forming process that provides freedom of design with respect to size, shape, and product quality.

Permanent Molding

In permanent mold casting, which also is referred to as gravity diecasting, a metal mold (or die) consisting of at least two parts is used repeatedly, usually for components that require relatively high production. Molds usually are made of cast iron, although steel, graphite, copper, and aluminum have been used as mold materials with varying degrees of success.

When molten metal is poured into a permanent mold, it cools more rapidly than in a sand mold and produces a finer-grained structure, a sounder and denser casting, and enhanced mechanical properties.

Diecasting Process

The diecasting process is used widely for high production of zinc, lead, tin, aluminum, copper, and magnesium cast components of intricate design. Molten alloy is poured manually or automatically into a shot well and injected into the die under pressure. An important factor in diecasting machine operation is the locking force (in tons), in which case the die is firmly closed against the injection pressure exerted by the plunger as it injects the molten metal.

There are two basic types of diecasting machines—hot chamber and cold chamber. The hot-chamber machine makes shots automatically and is used for low-melting-point materials, such as zinc alloys. The cold-chamber method, for higher-melting-point materials, such as aluminum and magnesium, holds molten metal at a constant temperature in a holding furnace of the bailout type. Metal is poured into the shot well either by hand or by automatic devices.

Vacuum diecasting sometimes is used to evacuate the die cavity. Its objectives are reduction of porosity, assisting metal flow in thin sections, and improving surface finish while at the same time permitting the use of injection pressures lower than those normally applied.

It should be noted that the meanings of the term *diecasting* in the United States and in European usage are different. Diecasting in Europe is any casting made in a metal mold. Pressure diecasting in Europe is a casting made in a metal mold in which the metal is injected under high pressure. In the United States, this is simply “diecasting.” Gravity diecasting in Europe is a casting poured in a metal mold by gravity, with no application of pressure. In the United States, this is “permanent molding.”

Investment Casting

In investment casting, a ceramic slurry is poured around a disposable pattern (normally of modified paraffin waxes, but also of plastics) and allowed to harden to form a disposable mold. The pattern is destroyed when it melts out during the firing of the ceramic mold. Later, molten metal is poured into the ceramic mold, and after the metal solidifies, the mold is broken up to remove the casting.

Two processes are used to produce investment casting molds—the solid mold and the ceramic shell methods. The ceramic shell method has become the predominant production technique today. The solid investment process is used primarily to produce dental and jewelry castings. Ceramic shell molds are used primarily for the investment casting of carbon and alloy steels, stainless steels,

heat-resistant alloys, and other alloys with melting points above 1093°C. The process can be mechanized.

Almost any degree of external and internal complexity can be accommodated, the only limitation is the state of the art in ceramic core manufacturing. Many problems inherent in producing a component by forging, machining, or multiple-piece fabricated assembly can be solved by utilizing the investment casting process. Sheet metal components, assembled by riveting, brazing, soldering, or welding, have been investment-cast as a single unit. Advantages realized include weight savings and better soundness.

Shell Molding Process

The essential feature of the shell, or Croning, process is the use of thin-walled molds and cores. Thermosetting resin-bonded silica sand is placed on a heated pattern for a predetermined length of time. Heating cures the resin, causing the sand grains to adhere to each other to form a sturdy shell that constitutes half the mold. Because of pattern costs, this method is best suited to volume production of cast metal components. The complete assembly is preheated to 177°C–204°C and the surface treated with a parting compound (silicone emulsion). The cured resin binders are nonhygroscopic, permitting prolonged storage of shell molds and allowing flexibility for production scheduling.

Castings made by the shell molding process may be more accurate dimensionally than conventional sand castings. A high degree of reproducibility as well as dimensional accuracy can be achieved with a minimum of dependence on the craftsmanship that sometimes is required with other molding processes. Only metal patterns and metal core boxes can be used in the shell process.

Lost Foam Casting

This process is also referred to as expanded polystyrene (EPS) molding, expandable pattern casting, evaporative foam casting, the full mold process, the cavityless casting process, and the cavityless EPS casting process. The process is an economical method of producing complex, close-tolerance castings, and uses unbonded sand; the pattern material is EPS.

The process involves attaching patterns to allow heating systems also made of EPS, then applying a refractory coating to the total assembly. Molten metal poured into the down-sprue vaporizes the polystyrene instantly and reproduces the pattern exactly. Gases formed from the vaporized pattern escape through the pattern coating, the sand, and the flask vents. A separate pattern is required for each casting.

To the designer, a major advantage of the process is that no cores are required. Cast-in features and reduced finishing stock usually are benefits of using the lost foam process. Inserts can be cast into the metal, and bimetallic castings can be made commercially.

Vacuum Molding

The vacuum molding process, popularly known as the V-process, is a sand molding process in which no binders are used to retain the shape of the mold cavity. Instead, unbonded sand is positioned between two sheets of thin plastic that are held in place by the application of a vacuum.

Replicast Process

The replicast process is said to overcome the shortcomings of another process that is prone to cause the formation of lustrous

carbon defects in steel castings, as well as undesirable carbon pickup. Outstanding features of the replicast process include surface finish comparable to that obtainable on investment castings, elimination of cores through the use of core inserts in pattern-making tooling, improved casting yields because of absence of spruce and runners, and high quality levels with regard to casting integrity and dimensional accuracy.

Other Casting Processes

Other molding systems and casting processes are used to make metal castings. For example, certain types of castings are produced in centrifugal casting machines.

Plaster mold casting is another specialized casting process used to produce nonferrous castings that is said to offer certain advantages over other processes.

Certain techniques are used to make castings in ceramic molds that are different from ceramic shell investment molding. The main difference is that the ceramic molds consist of a cope and a drag or, if the casting shape permits, a drag only.

Squeeze casting, also known as liquid-metal forging, is a process by which molten metal (ferrous or nonferrous) solidifies under pressure within closed dies positioned between the plates of a hydraulic press. The applied pressure and the instant contact of the molten metal with the die surface produce a rapid heat transfer condition that reportedly yields a pore-free, finer-grained casting with good mechanical properties.

CAT Scanning

See *computed tomography*.

Cat's Tongue (Surface)

A rough surface texture comprised of strong spikes and ridges separated by deep tapered pits. The texture often has a "lay," that is, it lies at an angle to the original surface and hence feels very rough when stroked in one direction but relatively smooth in the opposite direction, as does a cat's tongue. As the damage progresses the texture becomes increasingly coarse although, in terms of weight loss, the rate of damage may fall. The effect is characteristic of damage caused by repeated impact particles including water droplets. The damage mechanism is not a form of cutting abrasion but results from a fatigue action by the repeated impacts producing surface mechanical damage.

Catalyst

A substance capable of changing the rate of a reaction without itself undergoing any net change. A substance that markedly speeds up the *cure* of a plastic compound when added in minor quantity, compared to the amounts of primary reactants.

Small amounts of cocatalysts or promoters increase activity measurably. In the cracking of petroleum, activated carbon breaks the complex hydrocarbons into the entire range of fragments; activated alumina is more selective, producing a large yield of C₃ and C₄; and silica–alumina–zirconia is intermediate. *Contact catalysts* are the ones chiefly used in the chemical industry, and they may be in various forms. For bed reactors, the materials are pelleted. *Powdered catalysts* are used for liquid reactions such as the hydrogenation of oils. *Chemical catalysts* are usually liquid compounds, especially such acids as sulfuric and hydrochloric.

Various metals, especially platinum and nickel, are used to catalyze or promote chemical action in the manufacture of synthetics. Nitrogen in the presence of oxygen can be “fixed” or combined in chemicals at ordinary temperatures by the use of ruthenium as a catalyst. Acids may be used to aid in the polymerization of synthetic resins. Mineral soaps are used to speed up the oxidation of vegetable oils. Cobalt oxide is used for the oxidation of ammonia. Cobalt and thorium are used for synthesizing gasoline from coal. All of these are classified as *inorganic catalysts*. Sometimes, more complex chemicals are employed, silicate of soda being used as a catalyst for high-octane gasoline. In the use of *potassium persulfate*, $K_2S_2O_8$, as a catalyst in the manufacture of some synthetic rubbers, the material releases 5.8% active oxygen, and it is the nascent oxygen that is the catalyst. *Sodium methylate*, also called *sodium methoxide*, $CH_3 \cdot O \cdot Na$, used as a catalyst for ester-exchange reactions in the rearrangement of edible oils, is a white powder soluble in fats but violently decomposed in water. Transition-metal complexes, dispersed uniformly in solution, are called *homogeneous catalysts*. The most common ones are organo-metallic complexes, such as the carboxyls. They are more resistant to poisoning than solid *heterogeneous catalysts*, and they are highly active, specific, and selective. Magnetite, a magnetic iron ore, is used as a catalyst in the synthesis of ammonia. In a system from M.W. Kellogg Co., ruthenium, supported on a proprietary graphite structure, is more active, increasing ammonia production by 12%–16% over magnetite.

Metallocenes, organometallic coordination compounds obtained as cyclopentadienyl derivatives of a transition metal or metal hydride, are recent catalysts in the production of various plastics. Also referred to as single-site *catalysts*, they allow closer control of molecular weight and comonomer distribution, permitting monomers and comonomers previously considered incompatible to be combined. They also allow production of plastics in iso-tactic and syndiotactic forms and have been applied to polyethylene, ethylene copolymers, ethylene terpolymers (including ethylene-propylene-diene elastomers), polypropylene, and polystyrene.

Aluminum chloride, $AlCl_3$, in gray granular crystals, is used as a catalyst for high-octane gasoline and synthetic rubber and in the synthesis of dyes and pharmaceuticals. *Antimony trichloride*, $SbCl_3$, is a yellowish solid, used as a catalyst in petroleum processing to convert normal butane to isobutane. *Bead catalysts* of activated alumina have the alumina contained in beads of silica gel.

Molecular sieve zeolites are crystalline *aluminosilicates* of alkali and alkali-earth metals. The aluminum and silicon atoms form regular tetrahedral structures that have large voids interconnected by open three-dimensional channels. The microporous may amount to 50% of the volume, resulting in crystals with some of the highest internal surface areas. The alkaline cations are mobile and maybe ion-exchanged with metals with catalytic properties. Only reactants of the right molecular size may enter the channels and be catalyzed by the metal cations in the voids. As molecular sieves, zeolite catalysts are used as desiccants and absorbers and drying and purifying gases. Natural zeolites may be more effective than synthetic ones. *Catalyst carriers* are porous inert materials used to support the catalysts, usually in a bed through which a liquid or gas may flow. Materials used are generally alumina, silica carbide, or mullite, and they are usually in the form of graded porous granules or irregular polysurface pellets. High surface area, low bulk density, and good adherence of the catalyst are important qualities. Pellets are bonded with a ceramic that fuses around the granules with minute necks that hold the mass together as complex silicates and aluminates with no trace elements exposed to the action of a catalyst or chemicals. Catalyst carriers are usually bonded to make them about 40% porous. The pellets may be 15 mesh finer, or they may

be in sizes as large as 1 in. (2.5 cm). Platinum, palladium, and rhodium supported on activated alumina carriers are used in the catalytic converters of automobiles to clean up exhaust gases. A catalyst of precious metals supported on zeolite removes hydrocarbons, carbon monoxide, and nitrogen oxides from auto exhaust gases even in the presence of excess oxygen, as is the case for lean-burn engines. Developed by Mazda Motor of Japan, it could improve fuel efficiency of such engines by 5%–8%.

Catastrophic Failure

Sudden failure of a component or assembly that frequently results in extensive secondary damage to adjacent components or assemblies.

Catastrophic Period

In cavitation or liquid impingement erosion, a stage during which the erosion rate increases so dramatically that continued exposure threatens or causes gross disintegration of the exposed surface.

Catastrophic Wear

Sudden surface damage, deterioration, or change of shape caused by wear to such an extent that the life of the part is appreciably shortened or action is impaired.

Catchment Efficiency

See *collection efficiency*.

Catenary

A measure of the difference in length of reinforcing strands in a specified length of *roving* caused by unequal tension. The tendency of some strands in a taut horizontal roving to sag more than the others.

Cathode

The negative *electrode* of an *electrolytic cell* at which reduction is the principal reaction. (Electrons flow toward the cathode and the external circuit.) Typical cathodic processes are cations taking up electrons and being discharged, oxygen being reduced, and the reduction of an element or group of elements from a higher to a lower valence state. Contrast with *anode*.

Cathode Compartment

In an electrolytic cell, the enclosure formed by a diaphragm around the cathode.

Cathode Copper

Copper in slab form produced by electrolytic refining. It is subsequently re-melted to produce high conductivity grades such as electrolytic tough pitch, high conductivity copper, and oxygen-free high conductivity copper. It is also the basis for high conductivity copper castings and high conductivity alloys.

Cathode Efficiency

Current efficiency at the *cathode*.

Cathode Film

The portion of solution in immediate contact with the *cathode* during *electrolysis*.

Cathode-Ray Tube (CRT)

An electronic device in which a stream of electrons, that is, the negatively charged cathode ray, is formed and directed at a fluorescent screen. The path of the ray is deflected by electromagnetic coils to produce the screen display.

Cathodic Cleaning

Electrolytic cleaning in which the work is the *cathode*.

Cathodic Corrosion

Corrosion resulting from a cathodic condition of a structure usually caused by the reaction of an amphoteric metal and the alkaline products of *electrolysis*.

Cathodic Disbondment

The destruction of adhesion between a coating and its substrate by products of a *cathodic reaction*.

Cathodic Etching

See *ion etching*.

Cathodic Inhibitor

A corrosion protection, a chemical substance or mixture that prevents or reduces the rate of the cathodic or reduction reaction.

Cathodic Pickling

Electrolytic pickling in which the work is the *cathode*.

Cathodic Polarization

The change of the *electrode potential* in the active (negative) direction due to current flow. See also *polarization*.

Cathodic Protection

(1) Reduction of corrosion rate by shifting the *corrosion potential* of the electrode toward a less oxidizing potential by applying an external *electromotive force*. (2) Partial or complete protection of a metal from corrosion by making it a *cathode*, using either a galvanic or an impressed current. (3) Electrical currents can develop the metal components exposed to wet environments and corrosion will occur at the end anodic areas (see *electrochemistry*). However, attack may be prevented by inducing a reverse current that causes the component to be cathodic with respect to some external anode. One technique is to impose a DC electrical current from an external power source—termed Impressed Current cathodic protection. Alternatively, the component may be protected by attaching to it another metal that is more anodic. For example, steel was protected by zinc either in the form of plating, (galvanizing) or as large blocks of zinc bolted to, or buried close to, and in electrical circuit with, the component. These anodes will be progressively

consumed by corrosion, hence the term *Sacrificial Cathodic Protection* but the rate of anode loss, in practical cases, is acceptably economic and the main component will be preserved. Contrast with *anodic protection*.

Cathodic Reaction

Electrode reaction equivalent to a transfer of negative charge from the electronic to the ionic conductor. A cathode reaction is a reduction process.

Cathodoluminescence

A radioactive transition wherein low-energy light photons are really storing electron irradiation.

Catholyte

The *electrolyte* adjacent to the cathode of an electrolytic cell.

Cation

A positively charged ion that migrates through the electrolyte toward the *cathode* under the influence of a potential gradient. See also *anion* and *ion*.

Cationic Detergent

A detergent in which the *cation* is the active part.

Caul

In adhesive bonding, a sheet of material employed singly or in pairs in the hot or cold pressing of assemblies being bonded. A caul is used to protect either the faces of the assembly or the press platens, or both, against marring and staining in order to prevent sticking, facilitate press loading, impart a desired surface texture or finish, and provide uniform pressure distribution. A caul may be made of any suitable material such as aluminum, stainless steel, hardboard, fiberboard, or plastic, the length and width dimensions generally being the same as those of the plates of the press where it is used.

Caul Plates

In fabrication of composites, smooth metal plates, free of surface defects, that are the same size and shape as a composite lay-up, and that contact the lay-up during the curing process in order to transmit normal pressure and temperature, and to provide a smooth surface on the finish laminate.

Cauliflower

A growth of material on the exterior, particularly the top, of an ingot as a result of inverse segregation.

Caulk

See *caulking*.

Caulk Weld

See preferred term *seal weld*.

C

Caustic

(1) Burning or corrosive. (2) A hydroxide of a light metal, such as sodium hydroxide or potassium hydroxide.

Caustic Attack

Generally, any corrosion caused by caustic alkali. The term often refers specifically to the attack on the water side of steam generating tubes and power plants. The cause is excessive sodium hydroxide resulting either from the introduction of quantities well in excess of that required for normal feed water treatment or from local concentration affects. Factors promoting concentration are very high levels of heat input and bore irregularities such as deposits or the crevice produced when the internal projection of a flash butt weld is smeared along the bore rather than being cleanly cut away. When such factors are present, the tube bore facing toward the fire develops a persistent steam blanket rather than the normal bubbles of steam which can be swept away. The caustic concentrates in this area and the normally protective magnetite film is disrupted leading to severe corrosion and in some cases to hydrogen embrittlement. In some cases, the corrosive attack produces deep grooves along the tube leading to terms such as *caustic grooving* or *gouging*.

Caustic Cracking

A form of *stress-corrosion cracking* most frequently encountered in carbon steels or iron–chromium–nickel alloys that are exposed to concentrated hydroxide solutions at temperatures of (200°C–250°C) (400°F–480°F). Also known as caustic embrittlement.

Caustic Dip

A strongly alkaline solution into which metal is immersed for etching, for neutralizing acid, or for removing organic materials such as greases or paints.

Caustic Embrittlement

(1) An obsolete historical term denoting a form of *stress-corrosion cracking* most frequently encountered in carbon steels or iron–chromium–nickel alloys that are exposed to concentrated hydroxide solutions at temperatures of (200°C–250°C) (400°F–480°F). (2) Cracking, intergranular stress corrosion cracking of steel in caustic, alkaline, solutions. It usually only occurs above about 70°C and in fairly high alkaline conditions. However, it can be a serious problem in cases where the solution is now only 2 weeks to have any significant effect but where an inadvertent concentration mechanism is active. For example, to allow a concentration to develop in the leak path interface as water evaporates at the exterior face.

Caustic Quenching

Quenching with aqueous solutions of 5%–10% sodium hydroxide.

Caustic Soda

Sodium hydroxide.

Cavitating Disk Apparatus

A flow cavitation test device in which cavitating wakes are produced by holes in, or protuberances on, a disk rotating within a liquid-filled

chamber. Erosion test specimens are attached flush with the surface of the disk at the location where the bubbles are presumed to collapse.

Cavitation

The formation and collapse, within a liquid of cavities or bubbles that contain vapor or gas or both. In general, cavitation originates from a decrease in the static pressure in the liquid. It is distinguished in this way from boiling, which originates from an increase in the liquid temperature. There are certain situations where it may be difficult to make a clear distinction between cavitation in boiling, and the more general definition that is given here is therefore to be preferred. In order to erode a solid surface by cavitation, it is necessary for the cavitation bubbles to collapse on or close to that surface.

Cavitation Cloud

A collection of a large number of cavitation bubbles. The bubbles in a cloud are small, typically less than 1 mm in cross section.

Cavitation Corrosion

A process involving conjoint *corrosion* and *cavitation*.

Cavitation Damage

The degradation of a solid body resulting from its exposure to *cavitation*. This may include loss of material, surface deformation, or changes in properties or appearance.

Cavitation Erosion/Damage

The removal of metal from an immersed surface as a result of local severe pressure fluctuations associated with turbulent flow. Water subjected to a sudden pressure drop will form cavities, i.e., bubbles. These rapidly collapse producing shockwaves which damage adjacent surfaces by various mechanisms including a direct mechanical action, a fatigue action or by disrupting protective films. The development of local pits exacerbates cavity quality and size so metal loss is accelerated. Pumps and propellers are commonly affected.

Cavitation Tunnel

A flow cavitation test facility in which liquid is pumped through a pipe or tunnel, and cavitation is induced in a test section by conducting the flow through a constriction, or around an obstacle, or a combination of these.

Cavity (Metals)

The mold or die impression that gives a casting its external shape.

Cavity (Plastics)

The space inside a mold into which a resin or molding compound is poured or injected. The female portion of a mold. The portion of the mold that encloses the molded article (often referred to as the die). Depending on a number of such depressions, molds are designated as single cavity or multiple cavity.

Cavity Retainer Plates

In forming of plastics, plates in a mold that hold the cavities and forces. These plates are at the mold parting line and usually contain the guide pins and bushings. Also called force retainer plates.

CCP

Cubic close-packed crystallographic structure. Same as face-centered cubic.

CCT Diagram (Continuous Cooling Transformation Diagram)

See Isothermal Transformation Diagram.

Ceiling

The maximum that should not be exceeded in the process in question.

Cell

In honeycomb core, a cell is a single honeycomb unit, usually in a hexagonal shape.

Cell (Electrochemistry)

Electrochemical system consisting of an *anode* and a *cathode* immersed in an *electrolyte*. The anode and cathode may be separate metals or dissimilar areas on the same metal. The cell includes the external circuit, which permits the flow of electrons from the anode toward the cathode. See also *electrochemical cell*.

Cell (Plastics)

A single cavity formed by gaseous displacement in a plastic material. See also *cellular plastic*.

Cell Feed

The material supplied to the cell in the electrolytic production of metals.

Cell Size

The diameter of an inscribed circle within a cell of *honeycomb* core.

Cellular

A network comprising a large number of associated cells of broadly similar characteristics.

Cellular Adhesive

Synonym for foamed adhesive.

Cellular Plastic

A plastic with greatly decreased density because of the presence of numerous cells or bubbles dispersed throughout its mass. See also *cell (plastics)*, *foamed plastics*, and *syntactic cellular plastics*.

Cellulose

Cellulose is the main constituent of the structure of plants (natural polymer) that, when extracted, is employed for making paper, plastics, and in many combinations. Cellulose is made up of long-chain molecules in which the complex unit $C_5H_{10}O_6$ is repeated as many as 2000 times. It consists of glucose molecules with three hydroxyl groups for each glucose unit.

Cellulose is the most abundant of the nonprotein natural organic products. It is highly resistant to attack by the common microorganisms. However, the cellulose digests it easily, and this substance is used for making paper pulp, for clarifying beer and citrus juices, and for the production of citric acid and other chemicals from cellulose. Cellulose is a white powder insoluble in water, sodium hydroxide, or alcohol, but it is dissolved by sulfuric acid.

One of the simplest forms of cellulose used industrially is regenerated cellulose, in which the chemical composition of the finished product is similar to that of the original cellulose. It is made from wood or cotton pulp digested in a caustic solution. Cellophane is a regenerated cellulose in thin sheets for wrapping and other special uses include windings on wire and cable.

Cellulose Plastics

For plastics, pure cellulose from wood pulp or cotton linters (pieces too short for textile use) is reacted with acids or alkalis and alkyl halides to produce a basic flake. Depending upon the reactants, any one of four esters of cellulose (acetate, propionate, acetate butyrate, or nitrate) or a cellulose ether (ethyl cellulose) may result. The basic flake is used for producing both solvent cast films and molding powders.

Ethyl cellulose plastics are thermoplastic and are noted for their ease of molding, lightweight, and good dielectric strength, $15\text{--}20.5 \times 10^6$ V/m, and retention of flexibility over a wide range of temperature from -57°C to 66°C , the softening point. They are the toughest, the lightest, and have the lowest water absorption of the cellulosic plastics. But they are softer and lower in strength than cellulose-acetate plastics. Typical ethyl cellulose applications include football helmets, equipment housings, refrigerator parts, and luggage.

For molding powders, the flake is then compounded with plasticizers, pigments, and sometimes other additives. At this stage of manufacture, the plastics producer is able to adjust hardness, toughness, flow, and other processing characteristics and properties. In general, these qualities are spoken of together as flow grades. The flow of a cellulose plastic is determined by the temperature at which a specific amount of the material will flow through a standard orifice under a specified pressure. Manufacturers offer cellulosic molding materials in a large number of standard flow grades, and, for an application requiring a nonstandard combination of properties, are often able to tailor a compound to fit. Cellulose can be made into a film (cellophane) or into a fiber (rayon), but it must be chemically modified to produce a thermoplastic material.

Cellulosics are synthetic plastics, but they are not synthetic polymers; see Table C.8.

Because the cellulosics can be compounded with many different plasticizers in widely varying concentrations, property ranges are broad. These materials are normally specified by flow, defined in American Society for Testing and Materials (ASTM) D569, which is controlled by plasticizer content. Hard flows (low plasticizer content) are relatively hard, rigid, and strong. Soft flows (higher plasticizer content) are tough, but less hard, less rigid, and less strong. They also process at lower temperatures. Thus, within available

TABLE C.8
Properties of Cellulosics

ASTM or UL Test	Property	Cellulose Acetate	Cellulose Propionate	Cellulose Acetate Butyrate	Ethyl Cellulose
<i>Physical</i>

^b For 1/8 in. thick specimen.

property ranges listed, no one formulation can provide all properties to the maximum degree. Most commonly used formulations are in the middle flow ranges.

Molded cellulosic parts can be used in service over broad temperature ranges and are particularly tough at very low temperatures. Ethyl cellulose is outstanding in this respect. These materials have low specific heat and low thermal conductivity—characteristics that give them a pleasant feel.

Dimensional stability of butyrate, propionate, and ethyl cellulose is excellent. Plasticizers used in these materials do not evaporate significantly and are virtually immune to extraction by water. Water absorption (which causes dimensional change) is also low, with that of ethyl cellulose the lowest. The plasticizers in acetate are not as permanent as those in other plastics, however, and water absorption of this material is slightly higher.

Butyrate and propionate are highly resistant to water and most aqueous solutions except strong acids and strong bases. They resist nonpolar materials such as aliphatic hydrocarbons and ethers, but they swell or dissolve in low-molecular-weight polar compounds such as alcohols, esters, and ketones, as well as in aromatic and chlorinated hydrocarbons. Acetate is slightly less resistant than butyrate and propionate to water and aqueous solutions, and slightly more resistant to organic materials. Ethyl cellulose dissolves in all the common solvents for this polymer, as well as in such solvents as cyclohexane and diethyl ether. Like the cellulose esters, ethyl cellulose is highly resistant to water.

Although unprotected cellulose is generally not suitable for continuous outdoor use, special formulations of butyrate and propionate are available for such service. Acetate and ethyl cellulose are not recommended for outdoor use.

Applications

Acetate applications include extruded and cast film and sheet for packaging and thermoforming.

Cellulose Acetate

Cellulose acetate is an amber-colored, transparent material made by the reaction of cellulose and acetic acid or acetic anhydride in the presence of sulfuric acid.

It is thermoplastic and easily molded. The molded parts or sheets are tough, easily machined, and resistant to oils and many chemicals. In coatings and lacquers, the material is adhesive, tough, and resilient, and does not discolor easily. Cellulose acetate fiber for rayons can be made in fine filaments that are strong and flexible, nonflammable, mildew proof, and easily dyed. Standard cellulose acetate for molding is marketed in flake form.

In practical use, cellulose acetate moldings exhibit toughness superior to most other general-purpose plastics. Flame-resistant formulations are currently specified for small appliance housings and for other uses requiring this property. Uses for cellulose acetate molding materials include toys, buttons, knobs, and other parts where the combination of toughness and clear transparency is a requirement.

Extruded film and sheet of cellulose acetate packaging materials maintain their properties over long periods. Here also the toughness of the material is advantageously used in blister packages, skin packs, window boxes, and over wraps. It is a breathing wrap and is solvent and heat sealable.

Large end uses for cellulose acetate films and sheets include photographic film base, protective cover sheets for notebook pages and documents, index tabs, sound recording tape, as well as the laminating of book covers. The grease resistance of cellulose acetate sheet allows its use in packaging industrial parts with enclosed oil for protection.

For eyeglass frames, cellulose acetate is the material in widest current use. Because fashion requires varied and sometimes novel effects, sheets of clear, pearlescent, and colored cellulose acetate are laminated to make special sheets from which optical frames are fabricated.

The electrical properties of cellulosic films combined with their easy bonding, good aging, and available flame resistance bring about their specification for a broad range of electrical applications. Among these are as insulations for capacitors; communications cable; oil windings; in miniaturized components (where circuits may be vacuum metallized); and as fuse windows.

Cellulose triacetate is widely used as a solvent cast film of excellent physical properties and good dimensional stability. Used as photographic film base and for other critical dimensional work such as graphic arts, cellulose triacetate is not moldable.

Cellulose Propionate

Cellulose propionate, commonly called "CP" or propionate, is made by the same general method as cellulose acetate, but propionic acid is used in the reaction. Propionate offers several advantages over cellulose acetate for many applications. Because it is "internally" plasticized by the longer-chain propionate radical, it requires less plasticizer than is required for cellulose acetate of equivalent toughness.

Cellulose propionate absorbs much less moisture from the air and is thus more dimensionally stable than cellulose acetate. Because of better dimensional stability, cellulose propionate is often selected where metal inserts and close tolerances are specified.

Largest-volume uses for cellulose propionate are as industrial parts (automotive steering wheels, armrests, and knobs, etc.),

telephones, toys, findings, ladies' shoe heels, pen and pencil barrels, and toothbrushes.

Cellulose Acetate Butyrate

Commonly called butyrate or CAB, it is somewhat tougher and has lower moisture absorption and a higher softening point than acetate. CAB is made by the esterification of cellulose with acetic acid and butyric acid in the presence of a catalyst. It is particularly valued for coatings, insulating types, varnishes, and lacquers.

Special formulations with good weathering characteristics plus transparency are used for outdoor applications such as signs, light globes, and lawn sprinklers. Clear sheets of butyrate are available for vacuum-forming applications. Other typical uses include transparent dial covers, television screen shields, tool handles, and typewriter keys. Extruded pipe is used for electric conduits, pneumatic tubing, and low-pressure waste lines. Cellulose acetate butyrate also is used for cable coverings and coatings. It is more soluble than cellulose acetate and more miscible with gums. It forms durable and flexible films. A liquid cellulose acetate butyrate is used for glossy lacquers, chemical-resistant fabric coatings, and wire-screen windows. It transmits ultraviolet light without yellowing or hazing and is weather-resistant.

Cellulose Acetate Propionate

This substance is similar to butyrate in both cost and properties. Some grades have slightly higher strength and modulus of elasticity. Propionate has better molding characteristics, but lower weatherability than butyrate. Molded parts include steering wheels, fuel filter bowls, and appliance housings. Transparent sheeting is used for blister packaging and food containers.

Cellulose Nitrate

Cellulose nitrates are materials made by treating cellulose with a mixture of nitric and sulfuric acids, washing free of acid, bleaching, stabilizing, and dehydrating. For sheets, rods, and tubes it is mixed with plasticizers and pigments and rolled or drawn to the shape desired. The lower nitrates are very inflammable, but they do not explode like the high nitrates, and they are the ones used for plastics, rayons, and lacquers, although their use for clothing fabrics is restricted by law. The names *cellulose nitrate* and *pyroxylin* are used for the compounds of lower nitration, and the term *nitrocellulose* is used for the explosives.

Cellulose nitrate is the toughest of the thermoplastics. It has a specific gravity of 1.35–1.45, tensile strength of 41–52 MPa, elongation 30%–50%, compressive strength 137–206 MPa, Brinell hardness 8–11, and dielectric strength $9.9\text{--}21.7 \times 10^6$ V/m. The softening point is 71°C, and it is easy to mold and easy to machine. It also is readily dyed to any color. It is not light stable, and is therefore no longer used for laminated glass. It is resistant to many chemicals, but has the disadvantage that it is inflammable. The molding is limited to pressing from flat shapes.

Among thermoplastics, it is remarkable for toughness. For many applications today, however, cellulose nitrate is not practical because of serious property shortcomings: heat sensitivity, poor outdoor aging, and very rapid burning.

Cellulose nitrate cannot be injection-molded or extruded by the nonsolvent process because it is unable to withstand the temperatures these processes require. It is sold as films, sheets, rods, or tubes, from which end products may then be fabricated.

Cellulose nitrate yellows with age; if continuously exposed to direct sunlight, it yellows faster and the surface cracks. Its rapid burning must be considered for each potential application to avoid unnecessary hazard.

C

The outstanding toughness properties of cellulose nitrate lead to its continuing use in such applications as optical frames, shoe eyelets, ping-pong balls, and pen barrels.

Cellulosic Electrode (for Welding)

See electrode (welding).

Cellulosic Plastics

Plastics based on cellulose compounds, such as esters (cellulose acetate) and ethers (ethyl cellulose). See Table C.8.

Celsius

The SI recommended scale of temperature based on reference points including 0°C as a freezing point of water and 100°C as the boiling point of water. It is essentially identical to centigrade.

Cement

Cement is a synthetic mineral mixture that, when ground to a powder and mixed with water, forms a stone-like mass. This mass results from a series of chemical reactions whereby the crystalline constituents hydrate, forming a material of high hardness that is extremely resistant to compressive loading. The main uses of cement are in civil engineering, for which, since the late nineteenth century, it has become indispensable.

The history of cement dates back to the Romans, who found that mixtures of volcanic ash, lime, and clay would harden when wet, and who used it extensively to build structures. In 1757, it was found that burned and ground high calcific clays would harden when placed in water. In 1824, a patent was granted to a British bricklayer who formulated a new type of cement with improved hardness. Because the color of the material reminded him of the limestone on the Isle of Portland, he named the product portland cement. This cement was made by lightly calcining small batches of lime and clay and grinding the product of fine powder.

The modern manufacturing process is very basic and has not been radically changed since its inception except for the use of computer-controlled equipment, which has greatly improved the consistency of the final product. The four basic cement processing operations are: (1) quarrying and crushing of raw materials, (2) grinding to high fineness and carefully proportioning the mineral constituents, (3) pyroprocessing the raw materials in a rotary calciner, and (4) cooling and grinding the calcined product, or clinker, to obtain a fine powder.

There are four main compounds that compose portland cement: tricalcium silicate, $3\text{CaO} \cdot \text{SiO}_2$ (C_3S); dicalcium silicate, $2\text{CaO} \cdot \text{SiO}_2$ (C_2S); tricalcium aluminate, $3\text{CaO} \cdot \text{Al}_2\text{O}_3$ (C_4A); and tetracalcium aluminoferrite, $4\text{CaO} \cdot \text{Al}_2\text{O}_3 \cdot \text{Fe}_2\text{O}_3$ (C_3AF). In the United States, portland cements are manufactured to comply with the ASTM Standard Specification for Portland Cement, ASTM C150. This specification defines five main types of portland cement. Type I, which is made in the greatest quantity, is intended for general-purpose use when the special properties of the other types are not required. The special properties of the other types when used in concrete are: Type II, moderate sulfate resistance or moderate heat of hydration; Type III, high early strength; Type IV, low heat of hydration; Type V, high sulfate resistance. The chemical and physical differences between the types that produce their special properties lie in the proportions of the cement compounds and in the fineness to which the cement is ground.

Oxychloride cement, or *Sorel cement*, is composed of magnesium chloride, MgCl_2 , and calcined magnesia. It is strong and hard and, with various fillers, is used for floors and stucco. Magnesia cement is magnesium oxide, prepared by heating the chloride or carbonate to redness. When mixed with water, it sets to a friable mass but of sufficient strength for covering steam pipes or furnaces. It is usually mixed with asbestos fibers to give strength and added heat resistance. The term *85% magnesia* means 85% magnesia cement and 15% asbestos fibers. The cement will withstand temperatures up to 600°F (316°C).

Keene's cement, also known as *flooring cement* and *tiling plaster*, is a *gypsum cement*. It is made by burning gypsum at about 1100°F (593°C), to drive off the chemically combined water, grinding to a fine powder, and adding alum to accelerate the set. It will keep better than ordinary gypsum cement, has high strength, is white, and takes a good polish. *Parian cement* is similar, except that borax is used instead of alum. *Martin's cement* is made with potassium carbonate instead of alum. These cements are also called *hard-finish plaster*, and they will set very hard and white. They are used for flooring and to imitate tiling. An ancient natural cement is *pozzuolana cement*. It is a volcanic material found near Pozzuoli, Italy, and in several other places in Europe. It is a volcanic lava modified by steam or gases so that it is powdery and has acquired hydraulic properties. The chief components are silica and alumina, and the color varies greatly, being white, yellow, brown, or black. It has been employed as a construction cement since ancient times. *Slag cement* is made by grinding blast-furnace slag with portland cement. Pozzolans are siliceous materials which will combine with lime in the presence of water to form compounds having cementing properties. Fly ash is an artificial pozzolan composed principally of amorphous silica with varying amounts of the oxides of aluminum and iron and traces of other oxides. It is a fine, dark powder of spheroid particles produced as the by-product of combustion of pulverized coal, and collected at the base of the stack. As an admix, it improves the workability of concrete, and in large amounts its pozzolanic action adds to the compressive strength. A *fire-resistant cement*, developed by Arthur D. Little, Inc., is made of magnesium oxychlorides and magnesium oxysulfates. This inorganic resin foam cement contains 40%–50% bond water that is released when the material is exposed to high temperatures and absorbs heat. It is said not to burn, smoke, or produce poisonous fumes when subjected to a direct flame.

Cement Copper

In pure copper recovered by chemical deposition when iron (most often shredded steel scrap) is brought into prolonged contact with a dilute copper sulfate solution.

Cementation

The introduction of one or more elements into the outer portion of a metal object by means of the fusion at high temperature. See *carburizing*.

Cementation Process

An obsolete process in which wrought iron-activated charcoal is heated at about 900°C for a few days allowing carbon to diffuse into the low carbon iron to produce steel.

Cemented Carbides

Referred to as hard metals, belong to a class of hard, wear-resistant, refractory materials in which the hard carbide particles are bound together, or cemented, by a soft and ductile metal binder. The first cemented carbide produced was tungsten carbide (WC) with a cobalt binder. Over the years, the basic WC–Co material has been modified to produce a variety of cemented carbides, which are used in a wide range of applications, including metal cutting, mining, construction, rock drilling, metal-forming, structural components, and wear parts. Tungsten carbide-based materials with nickel or steel binders have also been produced for specialized applications.

Tungsten carbides are manufactured by powder metallurgy process consisting of (1) processing of the ore in the preparation of the WC powder, (2) preparation (ball milling) of WC powders and grade (alloying) powders, (3) the addition of suitable binder material, (4) powder consolidation, and (5) sintering of the compacted part at temperatures between 1300°C and 1600°C (2370°F and 2910°F), most often in vacuum. The sintered product can be directly used or can be ground, polished, and coated to suit a given application.

Approximately 50% of all carbide production is used for machining applications, and a wide variety of compositions are available. “Straight” grades, which consist of WC particles bonded with cobalt, generally contain 3%–12% Co and carbide grain sizes range from 0.5 to >5 µm. Alloy grades, or steel-cutting grades, contain titanium carbide (TiC), titanium carbonitride (TiCN), titanium nitride (TiN), and/or niobium carbide (NbC). Improved wear resistance of cemented carbide tools is achieved by multilayer hard coatings of TiC, TiCN, TiN, alumina (Al₂O₃), and occasionally hafnium carbide (HfC). These coatings are commonly applied by chemical vapor deposition.

Cemented carbides are also being used increasingly for nonmachining applications, such as metal and nonmetallic mining, oil and gas drilling, transportation and construction, metal-forming, structural and fluid-handling components, and forestry tools. Straight WC–Co grades are used for the majority of these applications. In general, cobalt contents range from 5% to 30% and WC grain sizes range from <1 to >8 µm.

Cementite

A hard (~800 HV), brittle compound of iron and carbon, known chemically as iron carbide and having the approximate chemical formula Fe₃C is characterized by an orthorhombic crystal structure. When it occurs as a phase in steel, the chemical composition will be altered by the presence of manganese and other carbide-forming elements. The highest cementite contents are observed in white cast irons, which are used in applications where high wear resistance is required.

Centane Number

A measure of the ignition quality of a fuel or petroleum product with reference to normal centane high-ignition quality fuel with an arbitrary number of 100.

Center Drilling

Drilling a short, conical hole in the end of a workpiece—a hole to be used to center the workpiece for turning on a lathe.

Center-Gated Mold

An injection or transfer mold in which the cavity is filled with plastic molding material, through a sprue or gate, directly into the center of the part.

Centering Plug

A plug fitting both spindle and cutter to ensure concentricity of the cutter mounting.

Centerless Grinding

Grinding the outside or inside diameter of a cylindrical piece which is supported on a work support blade instead of being held between centers and which is rotated by a so-called regulating or feed wheel.

Centerline Shrinkage

Shrinkage or porosity occurring along the central *plane or axis of a cast part*.

Centigrade

The original metric measure of temperature. Identical to Celsius in the SI system.

Centrifugal Casting (Plastics)

A method of forming thermoplastic resins in which the granular resin is placed in a rotatable container, heated to a molten condition by the transferor heat through the walls of the container, and rotated such that the centrifugal force induced will force the molten resin to conform to the configuration of the interior surface of the container. Used to fabricate large-diameter pipes and similar cylindrical items.

Centrifugal Castings

Centrifugal castings can be produced economically and with excellent soundness. They are used in the automotive, aviation, chemical, and process industries for a variety of parts having a hollow, cylindrical form or for sections or segments obtainable from such a form.

There are three modifications of centrifugal casting: (1) true centrifugal casting, (2) semicentrifugal casting, and (3) centrifuging.

1. True centrifugal casting is used for the production of cylindrical parts. The mold is rotated, usually in a horizontal plane, and the molten metal is held against the wall by centrifugal force until it solidifies.
2. Semicentrifugal casting is used for disk- and wheel-shaped parts. The mold is spun on a vertical axis, the metal is introduced at the center of the mold, and centrifugal force throws the metal to the periphery.
3. Centrifuging is used to produce irregular-shaped pieces. The method *differs from* static casting only in that the mold is rotated. Mold cavities are fastened at the periphery of a revolving turntable, the metal is introduced at the center, and thrown into the molds through radial ingates.

The nature of the centrifugal casting process ensures a dense, homogeneous cast structure free from porosity. Because the metal solidifies in a spinning mold under centrifugal force, it tends to be forced against the mold wall while impurities, such as sand, slag, and gases, are forced toward the inside of the tube. Another advantage of centrifugal casting is that recovery can run as high as 90% of the metal poured.

Certain types of castings are produced in centrifugal casting machines. There are essentially two types of those machines—the

horizontal type that rotates about a horizontal axis and the vertical type that rotates about a vertical axis. In general, horizontal machines are used to make pipe, tubes, bushings, cylinder sleeves, and other cylindrical or tubular castings that are simple in shape. Castings that are not cylindrical, or even symmetrical, can be made using vertical centrifugal casting machines.

Ferrous Castings

Centrifugal castings can be made of many of the ferrous metals—cast irons, carbon and low-alloy steels, and duplex metals.

Mechanical Properties

Regardless of alloy content, the tensile properties of irons cast centrifugally are reported to be higher than those of static castings produced from the same heat. Hydrostatic tests of cylinder liners produced by both methods show that centrifugally cast liners withstand about 20% more pressure than statically cast liners.

Freedom from directionality is one of the advantages that centrifugal castings have over forgings. Properties of longitudinal and tangential specimens of several stainless grades are substantially equal.

Shapes, Sizes, Tolerances

The external contours of centrifugal castings are not limited to circular forms. The contours can be elliptical, hexagonal, or fluted, for example. However, the nature of the true centrifugal casting process limits the bore to a circular cross section.

Iron and steel centrifugally cast tubes and cylinders are produced commercially with diameters ranging from 28.6 to 1500 mm, wall thickness of 0.25–102 mm, and in lengths up to 14.30 m. Generally it is impractical to produce castings with a ratio of the outside diameter to the inside diameter greater than about 4–1. The upper limit in size is governed by the cost of the massive equipment required to produce heavy castings.

As-cast tolerances for centrifugal castings are about the same as those for static castings. For example, tolerances on the outside diameter of centrifugally cast gray iron pipe range from 0.3 mm for 76 mm diameter to ± 0.6 mm for 1.2 m diameter. Inside-diameter tolerances are greater, because they depend not only on the mold diameter, but also on the quantity of metal cast; the latter varies from one casting to another. These tolerances are generally about 50% greater than those on outside diameters. Casting tolerances depend to some extent also on the shrinkage allowance for the metal being cast.

The figures given earlier apply to castings to be used in the unmachined state. For castings requiring machining, it is customary to allow 2.35–3.2 mm on small castings and up to 6.4 mm on larger castings. If the end-use requires a sliding fit, broader tolerances are generally specified to permit additional machining on the inside surface.

Cast Irons

Large tonnages of gray iron are cast centrifugally. The relatively low pouring temperatures and good fluidity of the common grades make them readily adaptable to the process. Various alloy grades that yield pearlitic, acicular, and chill irons are also used. In addition, specialty iron alloys such as “Ni-Hard” and “Ni-Resist,” have been cast successfully.

Carbon and Low-Alloy Steels

Centrifugal castings are produced from carbon steels having carbon contents ranging from 0.05% to 0.90%. Practically all of the AISI standard low-alloy grades have also been cast.

Small-diameter centrifugally cast tubing in the usual carbon steel grades is not competitive in price with mechanical tubing having normal wall thicknesses. However, centrifugally cast tubing is less expensive than statically cast material.

High-Alloy Steels

Most of the AISI stainless and heat-resisting grades can be cast centrifugally. A particular advantage of the process is its use in producing tubes and cylinders from alloy compositions that are difficult to pierce and to forge or roll.

The excellent ductility resulting in the stainless alloys from centrifugal casting makes it possible to reduce the rough cast tubes to smaller-diameter tubing by hot- or cold-working methods. For example, billets of 18-8 stainless steel, 114.5 mm outside diameter by 16 mm wall, have been reduced to 27-gauge capillary tubing without difficulty.

Duplex Metals

Centrifugal castings with one metal on the outside and another on the inside are also in commercial production. Combinations of hard and soft cast iron, carbon steel, and stainless steel have been produced successfully.

Duplex metal parts have been centrifugally cast by two methods. In one, the internal member of the pair is cast within a shell of the other. This method has been used to produce aircraft brake drums by centrifugally casting an iron liner into a steel shell.

In the second method, both sections of the casting are produced centrifugally; the metal that is to form the outer portion of the combination is poured into the mold and solidified and the second metal is introduced before the first has cooled. The major limitation of this method is that the solidification temperature of the second metal poured must be the same or lower than that of the first. This method is said to form a strongly bonded duplex casting.

The possibilities of this duplex method for producing tubing for corrosion-resistant applications and chemical pressure service have been developed.

Nonferrous Castings

Nonferrous centrifugal castings are produced from copper alloys, nickel alloys, and tin- and lead-base bearing metals. Only limited application of the process is made to light metals because it is questionable whether any property improvement is achieved; for example, differences in density between aluminum and its normal impurities are smaller than in the heavy metals and consequently separation of the oxides, a major advantage of the process, is not so successful.

Shapes, Sizes, Tolerances

As with ferrous alloys, the external shapes of nonferrous centrifugal castings can be elliptical, hexagonal, or fluted, as well as round. However, the greatest overall tonnage of nonferrous castings is produced in plain or semiplain cylinders. The inside diameter of the casting is limited to a straight bore or one that can be machined to the required contour with minimum machining cost.

Nonferrous castings are produced commercially in outside diameters ranging from about 25.4 mm to 1.8 m and in lengths up to 8.1 m. Weights of individual castings range from 0.2268 to 27,300 kg.

Although tolerances on as-cast parts are about the same as those for sand castings, most centrifugal castings are finished by machining. An advantage of centrifugal casting is that normally only a small machining allowance is required; this allowance varies from

as little as 1.53 mm on small castings to 6.4 mm on the outside diameter of large-diameter castings. A slightly larger machining allowance is required on the bore to permit removal of dross and other impurities that segregate in this area.

Copper Alloys

A wide range of copper casting alloys is used in the production of centrifugal castings. The alloys include the plain brasses, leaded brasses and bronzes, tin bronzes, aluminum bronzes, silicon bronzes, manganese bronzes, nickel silvers, and beryllium copper. The ASTM lists 32 copper alloys for centrifugal casting; in addition, there are a number of proprietary compositions that are regularly produced by centrifugal casting.

Most of these alloys can be cast without difficulty. Some trouble with segregation has been reported in casting the high leaded (over 10% lead) alloys. However, alloys containing up to 20% lead are being cast by some foundries; the requirements are (1) rapid chilling to prevent excessive lead segregation and (2) close control of speed.

The mechanical properties of centrifugally cast copper alloys vary with the composition and are affected by the mold material used. Centrifugal castings produced in chill molds have higher mechanical properties than those obtained by casting in sand molds. However, centrifugal castings made in sand molds have properties about 10% higher than those obtained on equivalent sections of castings produced in static sand molds. (Castings produced in centrifugal chill molds have properties 20%–40% higher than those produced in static sand molds.)

Nickel Alloys

Centrifugal castings of nickel 210, 213, and 305; “Monel” alloys 410, 505, and 506; and “Inconel” alloys 610 and 705 are commercially available in cylindrical tubes. Centrifugal castings are also produced from the heat-resisting alloys 60% nickel–12% chromium and 66% nickel–17% chromium. These alloys should behave like other materials and show improved density with accompanying improvement in mechanical properties. The nickel alloys are employed for service under severe corrosion, abrasion, and galling conditions.

Bearing Metals

Centrifugal casting is a standard method of producing lined bearings. Steel cylinders, after being cleaned, pickled, and tinned, are rotated while tin- or lead-base bearing alloys are cast into them. The composite cylinder is then cut lengthwise, machined, and finished into split bearings.

Centrifuge

A mechanism in which a material is spun either by having a swirl induced in it or by being contained in a vessel that is spun at high speed. In either case, the intention is to apply high gravitational forces that separate materials of different densities.

Centrifuge Casting

A casting technique in which mold cavities are spaced symmetrically about a vertical axial common downgate. The entire assembly is rotated about that axis during pouring and solidification.

Ceramic (Adjective)

(1) Of or pertaining to ceramics, that is, inorganic nonmetallic as opposed to organic or metallic. (2) Pertaining to products

manufactured from inorganic nonmetallic substances which are subjected to a high temperature during manufacture or use. (3) Pertaining to the manufacture or use of such articles or materials, such as ceramic process or ceramic science.

Ceramic Color Glaze

An opaque colored glass of satin or gloss finish obtained by spraying the clay body with a compound of metallic oxides, chemicals, and clays. It is fired at high temperatures, fusing the glaze to the body, making them inseparable.

Ceramic Fibers

Alumina–silica (Al_2O_3 – SiO_2) fibers, frequently referred to as ceramic fibers, are formed by subjecting a molten stream to a fiberizing force. Such force may be developed by high-velocity gas jets or rotors or intricate combinations of these. The molten stream is produced by melting high-purity Al_2O_3 and SiO_2 , plus suitable fluxing agents, and then pouring this melt through an orifice. The jet or rotor atomizes the molten stream and attenuates the small particles into fine fibers as supercooling occurs.

The resulting fibrous material is a versatile high-temperature insulation for continuous service in the 538°C–1260°C range. It thus bridges the gap between conventional inorganic fiber insulating materials (e.g., asbestos, mineral wool, and glass) and insulating refractories.

Al_2O_3 – SiO_2 fibers have a maximum continuous use temperature of 1093°C–1260°C, and a melting point of over 1760°C for extended periods of time, a phenomenon called devitrification occurs. This is a change in the orientation of the molecular structure of the material from the amorphous state (random orientation) to the crystalline state (definitely arranged pattern). Insulating properties are not affected by this phase change but the material becomes more brittle.

Most ceramic fibers have an Al_2O_3 content from 40% to 60%, and an SiO_2 content from 40% to 60%. Also contained in the fibers are from 1.5% to 7% oxides of sodium, boron, magnesium, calcium, titanium, zirconium, and iron.

Fibers as formed resemble a cotton-like mass with individual fiber length varying from short to 254 mm, and diameters from less than 1 to 10 μm . Larger-diameter fibers are produced for specific applications. In all processes, some unfiberized particles are formed that have diameters up to 40 μm .

Low density, excellent thermal shock resistance, and very low thermal conductivity are the properties of Al_2O_3 – SiO_2 fibers that make them an excellent high-temperature insulating material. Available in a variety of forms, ceramic fiber is in ever-increasing demand due to higher and higher temperatures now found in industrial and research processes.

Applications

Ceramic fibers were originally developed for application in insulating jet engines. Now, this is only one of numerous uses for this material. It can be found in aircraft and missile applications where a high-temperature insulating medium is necessary to withstand the searing heat developed by rockets and supersonic aircraft. Employed as a thermal-balance and pressure-distribution material, ceramic fiber in the form of paper has made possible the efficient brazing of metallic honeycomb-sandwich structures.

Successful trials have been conducted in aluminum processing where this versatile product in paper or molded form has been used

C

to transport molten metal with very little heat loss. Such fibrous bodies are particularly useful in these applications because they are not readily wet by molten aluminum.

Industrial furnace manufacturers utilize lightweight ceramic fiber insulation between firebrick and the furnace shell. It is also used for “hot topping,” heating element cushions, and as expansion joint packing to reduce heat loss and maintain uniform furnace temperatures.

Use of this new fiber as combustion chamber liners in oil-fired home heating units has materially improved heat-transfer efficiencies. The low heat capacity and light weight, compared to previously used firebrick, improve furnace performance and offer both consumer and manufacturer many benefits.

SiC Fibers

These fibers, capable of withstanding temperatures to about 1200°C, are manufactured from a polymer precursor. The polymer is spun into a fine thread, then pyrolyzed to form a 15 μm ceramic fiber consisting of fine SiC crystallites and an amorphous phase. An advantage of the process is that it uses technology developed for commercial fiber products such as nylon and polyester. Two commercial SiC fiber products are the Ube Industries Tyranno fiber and the Nippon Carbon Nicalon fiber.

Ceramic Glass Decorations

Ceramic glass enamels fused to glassware at temperatures above 245°C (800°F) to produce a decoration.

Ceramic Glass Enamels

Predominantly colored, silicate glass fluxes used to decorate glassware. Also referred to as ceramic enamels or glass enamels.

Ceramic Molding

A precision casting process that employs permanent patterns and fine-grain slurry for making molds. Unlike monolithic investment molds, which are similar in composition, ceramic molds consist of a *cope* and a *drag* or, if the casting shape permits a drag only.

Ceramic Printed Board

A printed board made from ceramic dielectric and cermet materials.

Ceramic Process

The production of articles or coatings from essentially inorganic, nonmetallic materials, the article or coating being made permanent and suitable for utilitarian and decorative purposes by the action of heat at temperatures sufficient to cause sintering, solid-state reactions, bonding, or conversion partially or wholly to the glassy state.

Ceramic Rod Flame Spraying

A thermal spraying process variation in which the material to be sprayed is a ceramic rod form. See also *flame spraying*.

Ceramic Tools

Cutting tools made from sintered, hot-pressed, or hot isostatically pressed alumina-based or silicon nitride-based ceramic materials. See also *alumina* and *silicon nitride*.

Ceramic Whiteware

A fired ware consisting of glazed or unglazed ceramic body which is commonly white and of fine texture. This term designates such product classifications as tile, china, porcelain, semi-vitreous ware, and earthenware. See also *traditional ceramics*.

Ceramic(s) (Noun)

Any of the class of inorganic nonmetallic products which are subjected to a high temperature during manufacture or use (high temperature usually means a temperature above a barely visible red, approximately 540°C, or 1000°F). Typically, but not exclusively, a ceramic is a metallic oxide, boride, carbide, or nitride, or a mixture or compound of such materials; that is, it includes anions that play important roles in atomic structures and properties.

See also *advanced ceramics*, *electronic ceramics*, *refractories*, *structural ceramics*, and *traditional ceramics*.

Ceramic–Matrix Composite

The class of materials known as ceramic–matrix composites, or CMCs, shows considerable promise for providing fracture-toughness values similar to those for metals such as cast iron. Two kinds of damage-tolerant ceramic–ceramic composites have been developed. One incorporates a continuous reinforcing phase, such as a fiber; the other, a discontinuous reinforcement, such as whiskers. The major difference between the two is in their failure behavior. Continuous-fiber-reinforced materials do not fail catastrophically. After matrix failure, the fiber can still support a load. A fibrous failure is similar to that which occurs in wood.

CMCs are candidate materials for high-performance engines and wear-resistant parts. Interest in ceramic composites has been stimulated by the realization that carbon–carbon composites (CCC) are difficult to protect from oxidation, and that metal–matrix composites (MMCs) have end-use temperature limitations that are below the level needed for engine components.

A wide variety of reinforcing materials, matrices, and corresponding processing methods have been studied. The most successful fiber-reinforced composites have been produced by hot pressing, chemical vapor infiltration, or directed metal oxidation, which is a process that uses accelerated oxidation reactions of molten metals to grow ceramic matrices around preplaced fiber or reinforcement material preforms. Much of the work has been on glass and glass-ceramic matrices reinforced with carbon fibers. Because of the low axial coefficient of thermal expansion (CTE) of carbon fibers and the requirements for CTE matching, the more successful composites have been produced with low CTE matrices, such as borosilicate glass ($\text{CTE} = 3.5 \times 10^{-6} \text{ K}^{-1}$) and lithium aluminosilicate glass-ceramics ($\text{CTE} = 1.5 \times 10^{-6} \text{ K}^{-1}$). Other fiber-reinforced ceramic composites include silicon carbide fibers in SiC produced by chemical vapor infiltration and deposition, and SiC fiber reinforced alumina (Al_2O_3) and zirconium diboride (ZrB_2) reinforced zirconium carbide (ZrC) composites produced by directed metal oxidation. Multidirectionally reinforced ceramics, such as fused quartz reinforced silica and Al_2O_3 reinforced silica, have also been produced, the latter material being used for larger radome structures on ballistic missiles.

Incorporating whiskers into a ceramic matrix improves resistance to crack growth, making the composite less sensitive to flaws. These materials are commonly described as being flaw tolerant. However, once a crack begins to propagate, failure is catastrophic.

Composed of fine equiaxed Al_2O_3 grains and needle-like SiC whiskers, $\text{SiC}_w\text{-Al}_2\text{O}_3$ composites exhibit promising fracture toughness (6.5 MPa $\sqrt{\text{m}}$, or 5.9 ksi $\sqrt{\text{in.}}$) and strength (600 MPa or 57 ksi) properties. $\text{SiC}_w\text{-Al}_2\text{O}_3$ composites have been used in cutting-tool applications. Composites with whisker loadings higher than 8 vol% must be hot pressed.

Of particular importance to the technology of toughened ceramics has been the development of high-temperature SiC reinforcements.

SiC Filaments

SiC filaments are prepared by chemical vapor deposition. A thick layer of SiC is deposited on a thin fiber substrate of tungsten or carbon. Diameter of the final product is about 140 μm .

Although developed initially to reinforce aluminum and titanium matrices SiC filaments have since been used as reinforcement in Si_3N_4 .

SiC Whiskers

SiC whiskers consist of a fine (0.5–5 μm -diameter) single-crystal structure in lengths to 100 μm . The material is strong (to 15.9 GPa) and is stable at temperatures to 1800°C. Whiskers can be produced by heating SiO_2 and carbon sources with a metal catalyst in the proper environments.

Although these materials are relatively new, at least one successful commercial product is already being marketed. An SiC-whisker-reinforced Al_2O_3 cutting-tool material is being used to machine nickel-based superalloys. In addition, considerable interest has been generated in reinforcing other matrices such as mullite, SiC, and Si_3N_4 for possible applications in automotive and aerospace industries.

The excellent high-temperature strength, oxidation resistance, thermal shock resistance, and fracture toughness of silicon nitride has led to the development of SiC_w reinforced Si_3N_4 . The major phase, Si_3N_4 offers many favorable properties, and the SiC whiskers provide significant improvement in the fracture toughness of the composite. Whisker-reinforced Si_3N_4 is a leading candidate material for hot-sections of ceramic-engine components.

DIMOX Process

CMCs are steadily moving from the laboratory to initial commercial applications. For example, engineers are currently evaluating these materials for use in the hot gas zones of gas turbine engines, because ceramics are known for their strength and favorable creep behavior at high temperatures. Advanced ceramics, for example, can potentially be used at temperatures 204°C–482°C above the maximum operating temperature for superalloys.

Until recently, however, there has been more evaluation than implementation of advanced ceramics for various reasons. Monolithic or single-component ceramics, for example, lack the required damage tolerance and toughness. Engine designers are put off by the potential of ceramic material for catastrophic, brittle failures. Although many CMCs have greater toughness, they are also difficult to process by traditional methods, and may not have the needed long-term high-temperature resistance.

A relatively new method for producing CMCs developed by Lanxide Corp. promises to overcome the limitations of other

ceramic technologies. Called the DIMOX directed metal oxidation process, it is based on the reaction of a molten metal with an oxidant, usually a gas, to form the ceramic matrix. Unlike the sintering process, in which ceramic powders and fillers are consolidated under heat, directed metal oxidation grows the ceramic matrix material around the reinforcements.

Examples of ceramic matrices that can be produced by the DIMOX directed metal oxidation process include Al_2O_3 , Al_2Ti_5 , AlN, TiN, ZrN, TiC, and ZrC. Filler materials can be anything chemically compatible with the ceramic, parent metal, and growth atmosphere.

The first step in the process involves making a shaped preform of the filler material. Preforms consisting of particles are fabricated with traditional ceramic-forming techniques, while fiber preforms are made by weaving, braiding, or laying up woven cloth. Next, the preform is put in contact with the parent metal alloy. A gas-permeable growth barrier is applied to the surfaces of this assembly to limit its shape and size.

The assembly, supported in a suitable refractory container, is then heated in a furnace. For aluminum systems, temperatures typically range from 899°C to 1149°C. The parent metal reacts with the surrounding gas atmosphere to grow the ceramic reaction product through and around the filler to form a CMC.

Capillary action within the growing ceramic matrix continues to supply molten alloy to the growth front. There, the reaction continues until the growing matrix reaches the barrier. At this point, growth stops, and the part is cooled to ambient temperature. To recover the part, the growth barrier and any residual parent metal are removed. However, some of the parent metal (5%–15% by volume) remains within the final composite in micron-sized interconnected channels.

Traditional ceramic processes use sintering or hot pressing to make a solid CMC out of ceramic powders and filler. Part size and shapes are limited by equipment size and the shrinkage that occurs during densification of the powders can make sintering unfeasible. Larger parts pose the biggest shrinkage problem. Advantages of the directed metal oxidation process include low shrinkage because matrix formation occurs by a growth process. As a result, tolerance control and large part fabrication can be easier with directed metal oxidation.

In addition, the growth process forms a matrix whose grain boundaries are free of impurities or sintering aids. Traditional methods often incorporate these additives, which reduce high-temperature properties. And cost comparisons show the newer process is a promising replacement for traditional methods.

Ceramic-Metal Coating

A mixture of one or more ceramic materials in combination with a metallic phase applied to a metallic substrate which may or may not require heat treatment prior to service. This term may also be used for coatings applied to nonmetallic substrates, for example, graphite.

Ceramics

Ceramics are inorganic, nonmetallic materials processed or consolidated at high temperature. Ceramics, one of the three major material families, are crystalline compounds of metallic and nonmetallic elements. The ceramic family is large and varied, including such materials as refractories, glass, brick, cement and plaster, abrasives, sanitaryware, dinnerware, artware, porcelain enamel, ferroelectrics, ferrites, and dielectric insulators. There are other materials that, strictly speaking, are not ceramics, but that nevertheless are often

included in this family. These are carbon and graphite, mica, and asbestos. Also, intermetallic compounds, such as aluminides and beryllides, which are classified as metals, and cermets, are usually thought of as ceramic materials because of similar physical characteristics to certain ceramics.

Ceramic materials can be subdivided into traditional and advanced ceramics. Traditional ceramics include clay-base materials such as brick, tile, sanitaryware, dinnerware, clay pipe, and electrical porcelain. Common-usage glass, cement, abrasives, and refractories are also important classes of traditional ceramics.

Advanced materials technology is often cited as an “enabling” technology, enabling engineers to design and build advanced systems for applications in fields such as aerospace, automotive, and electronics. Advanced ceramics are tailored to have premium properties through application of advanced materials science and technology to control composition and internal structure. Examples of advanced ceramic materials are Si_3N_4 , SiC , toughened ZrO_2 , ZrO_2 -toughened Al_2O_3 , AlN , PbMg niobate, PbLa titanate, SiC -whisker-reinforced Al_2O_3 , carbon-fiber-reinforced glass ceramic, SiC -fiber-reinforced SiC , and high-temperature superconductors. Advanced ceramics can be viewed as a class of the broader field of advanced materials, which can be divided into ceramics, metals, polymers, composites, and electronic materials. There is considerable overlap among these classes of materials.

Advanced ceramics can be subdivided into structural and electronic ceramics based on primary function or application. Optical and magnetic materials are usually included in the electronic classification. Structural applications include engine components, cutting tools, bearings, valves, wear- and corrosion-resistant parts, heat exchangers, fibers and whiskers, and biological implants. The electronic-magnetic-optic functions include electronic substrates, electronic packages, capacitors, transducers, magnets, waveguides, lamp envelopes, displays, sensors, and ceramic superconductors. Thermal insulation, membranes, and filters are important advanced ceramic product areas that do not fit well into either the structural or the electronic class of advanced ceramics.

Advanced ceramics are differentiated from traditional ceramics such as brick and porcelain by their higher strength, higher operating temperatures, improved toughness, and tailorable properties. Also known as engineered ceramics, these materials are replacing metals in applications where reduced density and higher melting points can increase efficiency and speed of operation. The nature of the bond between ceramic particles helps differentiate engineering ceramics from conventional ceramics. Most particles within an engineering ceramic are self-bonded, that is, joined at grain boundaries by the same energy-equilibrium mechanism that bonds metal grains together. In contrast, most nonengineering ceramic particles are joined by a so-called ceramic bond, which is a weaker, mechanical linking or interlocking of particles. Generally, impurities and nonengineering ceramics prevent the particles from self-bonding.

A broad range of metallic and nonmetallic elements are the primary ingredients in ceramic materials. Some of the common metals are aluminum, silicon, magnesium, beryllium, titanium, and boron. Nonmetallic elements with which they are commonly combined are O_2 , carbon, or N_2 . Ceramics can be either simple, one-phase materials composed of one compound, or multiphase, consisting of a combination of two or more compounds. Two of the most common are single oxide ceramics, such as alumina (Al_2O_3) and magnesia (MgO), and mixed oxide ceramics, such as cordierite (magnesia alumina silica) and forsterite (magnesia silica). Other newer ceramic compounds include borides, nitrides, carbides, and silicides. Macrostructurally, there are essentially three types of

ceramics: crystalline bodies with a glassy matrix; crystalline bodies, sometimes referred to as holocrystalline; and glasses.

The specific gravities of ceramics range roughly from 2 to 3. As a class, ceramics are low-tensile-strength, relatively brittle materials. A few have strengths above 172 MPa, but most have less than that. Ceramics are notable for the wide difference between their tensile and compressive strengths. They are normally much stronger under compressive loading than in tension. It is not unusual for a compressive strength to be 5–10 times that of the tensile strength. Tensile strength varies considerably depending on composition and porosity.

One of the major distinguishing characteristics of ceramics, as compared to metals, is their almost total absence of ductility. They fail in a brittle fashion. Lack of ductility is also reflected in low impact strength, although impact strength depends to a large extent on the shape of the part. Parts with thin or sharp edges or curves and with notches have considerably lower impact resistance than those with thick edges and gently curving contours.

Ceramics are the most rigid of all materials. A majority of them are stiffer than most metals, and the modulus of elasticity in tension of a number of types runs as high as 0.3–0.4 million MPa compared with 0.2 million MPa for steel. In general, they are considerably harder than most other materials, making them especially useful as wear-resistant parts and for abrasives and cutting tools.

Ceramics have the highest known melting points of materials. Hafnium and TaC, for example, have melting points slightly above 3870°C , compared to 3424°C for tungsten. The more conventional ceramic types, such as Al_2O_3 , melt at temperatures above 1927°C , which is still considerably higher than the melting point of all commonly used metals. Thermal conductivities of ceramic materials fall between those of metals and polymers. However, thermal conductivity varies widely among ceramics. A two-order magnitude of variation is possible between different types, or even between different grades of the same ceramic. Compared to metals and plastics, the thermal expansion of ceramics is relatively low, although like thermal conductivity it varies widely between different types and grades. Because the compressive strengths of ceramic materials are 5–10 times greater than tensile strength, and because of relatively low heat conductivity, ceramics have fairly low thermal-shock resistance. However, in a number of ceramics, the low thermal expansion coefficient succeeds in counteracting to a considerable degree the effects of thermal conductivity and tensile–compressive-strength differences.

Practically all ceramic materials have excellent chemical resistance, and are relatively inert to all chemicals except hydrofluoric acid and, to some extent, hot caustic solutions. Organic solvents do not affect them. Their high surface hardness tends to prevent breakdown by abrasion, thereby retarding chemical attack. All technical ceramics will withstand prolonged heating at a minimum of 999°C . Therefore, atmospheres, gases, and chemicals cannot penetrate the material surface and produce internal reactions that are normally accelerated by heat.

Unlike metals, ceramics have relatively few free electrons and therefore are essentially nonconductive and considered to be dielectric. In general, dielectrical strengths, which range between 7.8×10^6 and 13.8×10^6 V/m, are lower than those of plastics. Electrical resistivity of many ceramics decreases rather than increases with an increase in impurities, and is markedly affected by temperature.

Fabrication Process

A wide variety of processes are used to fabricate ceramics. The process chosen for a particular product is based on the material, shape, complexity, property requirements, and cost. Ceramic fabrication

processes can be divided into four generic categories: powder, vapor, chemical, and melt processes.

Powder Processes

Transitional clay-base ceramics and most refractories are fabricated by powder processes as are the majority of advanced ceramics. Powder processing involves a number of sequential steps. These are preparation of the starting powders, forming the desired shape (green forming), removal of water and organics, heating with or without application of pressure to densify the powder, and finishing.

Vapor Processes

The primary vapor processes used to fabricate ceramics are chemical vapor deposition (CVD) and sputtering. Vapor processes have been finding an increasing number of applications. CVD involves bringing gases containing the atoms to contact the ceramic and then into contact with a heated surface, where the gases react to form a coating. This process is used to apply ceramic coatings to metal and tungsten carbide cutting tools as well as to apply a wide variety of other coatings for wear, electronic, and corrosion applications. CVD can also be used to form monolithic ceramics by building up thick coatings. A form of CVD known as chemical vapor infiltration (CVI) has been developed to infiltrate and coat the surfaces of fibers in woven preforms.

Several variations of sputtering and other vacuum-coating processes can be used to form coatings of ceramic materials. The most common process is reactive sputtering, used to form coatings such as TiN on tool steel.

Chemical Processes

A number of different chemical processes are used to fabricate advanced ceramics. The CVD process described earlier as a vapor process is also a chemical process. Two other chemical processes finding increasing application in advanced ceramics are polymer pyrolysis and sol-gel technology.

Melt-Processes

These are used to manufacture glass, to fuse-cast refractories for use in furnace linings, and to grow single crystals. Thermal spraying can also be classified as a melt process. In this process a plasma-spray gun is used to apply ceramic coatings by melting and spraying powders onto a substrate.

Metal Oxide Ceramics

Although most metals form at least one chemical compound with O_2 , only a few oxides are useful as the principal constituent of a ceramic. And of these, only three are used in their fairly pure form as engineering ceramics: Al_2O_3 , BeO, and ZrO_2 .

The natural alloying element in the Al_2O_3 system is SiO_2 . However, Al_2O_3 s can be alloyed with chromium (which forms a second phase with the Al_2O_3 and strengthens the ceramic) or with various oxides of silicon, magnesium, or calcium.

Al_2O_3 s serve well at temperatures as high as 1925°C provided they are not exposed to thermal shock, impact, or highly corrosive atmospheres. Above 2038°C, strength of Al_2O_3 drops. Consequently, many applications are in steady-state, high-temperature environments, but not where abrupt temperature changes would cause

failure from thermal shock. Al_2O_3 s have good creep resistance up to about 816°C above which other ceramics perform better. In addition, Al_2O_3 s are susceptible to corrosion from strong acids, steam, and sodium. See *Aluminum*.

BeO ceramics are efficient heat dissipaters and excellent electrical insulators. They are used in electrical and electronics applications, such as microelectric substrates, transistor bases, and resistor cores. BeO has excellent thermal shock resistance (some grades can withstand 816°C/s changes), a very low coefficient of thermal expansion (CTE), and a high thermal conductivity. It is expensive, however, and is an allergen to which some persons are sensitive. See *Beryllium*.

ZrO_2 is used primarily for its extreme inertness to most metals. ZrO_2 ceramics retain strength nearly up to their melting point—well over 2205°C, the highest of all ceramics. Applications for fused or sintered ZrO_2 include crucibles and furnace bricks. See *Zirconium*.

Transformation-toughened ZrO_2 ceramics are among the strongest and toughest ceramics made. These materials are of three main types: Mg-PSZ (ZrO_2 partially stabilized with MgO), Y-TZP (Y_2O_3 stabilized tetragonal ZrO_2 poly crystals), and ZTA (ZrO_2 -toughened Al_2O_3).

Applications of Mg-PSZ ceramics are principally in low- and moderate-temperature abrasive and corrosive environments—pump and valve parts, seals, bushings, impellers, and knife blades. Y-TZP ceramics (stronger than Mg-PSZ but less flaw tolerant) are used for pump and valve components requiring wear and corrosion resistance in room-temperature service. ZTA ceramics, which have lower density, better thermal shock resistance, and lower cost than the other two, are used in transportation equipment where they need to withstand corrosion, erosion, abrasion, and thermal shock.

Many engineering ceramics have multioxide crystalline phases. An especially useful one is cordierite ($MgO-Al_2O_3-SiO_3$), which is used in cellular ceramic form as a support for a wash-coat and catalyst in catalytic converters in automobile emission systems. Its low CTE is a necessary property for resistance to thermal fracture.

Glass Ceramics

Glass ceramics are formed from molten glass and subsequently crystallized by heat treatment. They are composed of several oxides that form complex, multiphase microstructures. Glass ceramics do not have the strength-limiting porosity of conventional sintered ceramics. Properties can be tailored by control of the crystalline structure in the host glass matrix. Major applications are cooking vessels, tableware, smooth cooktops, and various technical products such as radomes.

The three common glass ceramics, Li-Al- SiO_3 (LAS, or beta spodumene), Mg-Al- SiO_3 (MAS, or cordierite), and Al- SiO_3 (AS, or aluminous keatite), are stable at high temperatures, have near-zero CTEs, and resist various forms of high-temperature corrosion, especially oxidation. LAS and AS have essentially no measurable thermal expansion up to 427°C. The high SiO_2 content of LAS is responsible for the low thermal expansion, but the SiO_2 also decreases strength. LAS is attacked by sulfur and sodium.

MAS is stronger and more corrosion resistant than LAS. A multiphased version of this material, MAS with $AlTiO_3$, has good corrosion resistance up to 1093°C.

AS, produced by leaching lithium out of LAS particles prior to forming, is both strong and corrosion resistant. It has been used, for example, in an experimental rotating regenerator for a turbine engine.

A proprietary ceramic (**Macor**) called machinable glass ceramic (MGC), is about as strong as Al_2O_3 . It also has many of

the high-temperature and electrical properties of the glass ceramics. The main virtue of this material is that it can be machined with conventional tools. It is available in bars, or it can be rough-formed, then finish-machined. Machined parts do not require firing.

A similar glass ceramic is based on chemically machinable glass that, in its initial state, is photosensitive. After the glass is sensitized by light to create a pattern, it is chemically machined (etched) to form the desired article. The part can then be used in its glassy state, or it can be fired to convert it to a glass ceramic. This material/process combination is used where precision tolerances are required and where a close match to thermal expansion characteristics of metals is needed. Typical applications are sliders for disk-memory read/write heads, wire guides for dot-matrix printers, cell sheets for gas-discharge displays, and substrates for thick-film and thin-film metallization.

Another ceramic-like material, glass-bonded mica, the moldable/machinable ceramic, is also called a "ceramoplastic" because its properties are similar to those of ceramics, but it can be machined and molded like a plastic material. A glass/mica mixture is pressed into a preform, heated to make the glass flow, then transfer- or compression-molded to the desired shape. The material is also formed into sheets and rods that can be machined with conventional carbide tooling. No firing is required after machining.

The thermal expansion coefficient of glass-bonded mica is close to that of many metals. This property, along with its extremely low shrinkage during molding, allows metal inserts to be molded into the material and also ensures close dimensional tolerances. Molding tolerances as close as ± 0.01 mm/mm can be held. Continuous service temperatures for glass-bonded mica range from cryogenic to 371°C or 704°C depending upon material grade.

Aluminum-Ceramic Coatings

These coatings are used to protect aircraft-turbine and other turbomachinery parts from corrosion and heat at temperatures to 2000°F (1093°C) and greater. For compressor applications in ground-based turbines, aluminum-filled, chromate-phosphate coatings sealed with a ceramic topcoat have more than doubled service life. Aluminum-ceramic coatings are also alternatives to cadmium plating of fasteners and other products and used for galvanic protection of dissimilar materials. *Nickel-ceramic coatings*, with silicon carbide or silicon carbide and phosphorus added to the nickel matrix for hardness and hexagonal boron nitride or silicon nitride for lubricity are used in Japan on cylinder bores and pistons of outboard-marine, motorcycle, and snowmobile engines to increase wear resistance. Paintable ceramic coatings, especially of Zyp Coatings, Inc., combined corrosion resistance with heat resistance to 2000°F (1093°C).

Piezoelectric Ceramics

These ceramics produce voltage proportional to applied mechanical force and, conversely, mechanical force when electric voltage is applied. The ceramics are classified as materials into hard, soft, and custom groups. *Lead zirconate titanate* ceramics encompass both "hard" and "soft" groups. The hard, such as PZT-4, 4D, and 8, can withstand high levels of electrical excitation and stress. They are suited for high-voltage or high-powered generators and transducers. The soft, such as PZT-5A, 4B, 5H, 5J, and 5R as well as 7A and 7D, feature greater sensitivity and permittivity. Under high drive conditions, however, they are susceptible to self-heating beyond their operating temperature range. They are used in sensors, low-power motor-type transducers, receivers, low-power generators,

hydrophones, accelerometers, vibration pickups, inkjet printers, and towed array lines. Modified **lead metaniobate**, PN-1 and 2, features higher operating temperatures and is used in accelerometers, flow detectors, and thickness gages. All are available as rods, tubes, disks, plates, rings, and blocks as well as in custom shapes.

Because of their extreme hardness, hot hardness, wear resistance, and chemical inertness, ceramics are used for cutting tools, mainly in the form of inserts fixed to a tool-holder, to increase machining speeds or metal-removal rates, and to enhance machining of certain metals and alloys relative to traditional cutting-tool materials. On the other hand, the materials are more costly and brittle. The most commonly used ceramics for cutting tools are based on alumina or silicon nitride. Various other ceramics are added to the powder mix to enhance sintering mechanical properties, toughness primarily. Principal alumina-based materials, for example, contain titanium carbide, zirconia, or silicon carbide. Other additives include titanium nitride, titanium boride, titanium carbonitride, and zirconium carbonitride. Silicon nitride is generally stronger and tougher than the alumina but alumina, aluminum nitride, or silica is required as a sintering additive to achieve dense material. *SiALONs* consist of various amounts of alumina and silicon nitride, sometimes with zirconia or yttria additives.

Larsenite, of Blasch Precision Ceramics, Inc., is a ceramic composite of alumina and silicon carbide. It is more resistant to thermal shock than alumina and resists oxidation at higher temperatures over 3000°F (1649°C) than the carbide. It is made by firing alumina and a particular grain size of silicon carbide, which then forms a lattice and improves the thermal shock resistance of the alumina. The composite has been used instead of fused silica for nozzles used in atomizing metals into powder. *Sulfide ceramics*, developed at Argonne National Laboratory, hold promise for effective bonding of difficult-to-join materials, such as ceramics to metals. Because they form at lower temperatures than traditional welds, joints are stronger and less brittle. Materials having coefficients of thermal expansion differing by as much as 200% have been joined. The ceramics are candidates for use in lithium-iron sulfide batteries being developed for battery-powered cars.

Ecoceramics is the term given to *silicon carbide* ceramics developed from renewable resources and environmental waste (natural wood and sawdust) at the National Aeronautics and Space Administration Glenn Research Center. Parts are to net shape, pyrolyzed at 1800°F (982°C), and infiltrated with molten silicon or silicon alloys.

Cereal

An organic *binder*, usually cornflower.

Cerium

A chemical element, cerium (Ce) is the most abundant metallic element of the rare earth group in the periodic table. Cerium occurs mixed with other rare earths in many minerals, particularly monazite and bastnaesite, and is found among the products of the fission of uranium, thorium, and plutonium.

It is a strong reducing agent used as a getter and thermionic valves and in a number of refining processes usually in the form of *Misch Metal*, and imprecise mixture of about 50% cerium and other rare earths. With 50% iron, it forms a pyrophoric alloy for products such as cigarette lighter "flints." Small additions are made to aluminum and magnesium to improve their strength and ductility and to cast irons to promote the formation of nodular graphite. See *cast iron*.

Ceric oxide, CeO_2 , is the oxide usually obtained when cerium salts of volatile acids are heated. CeO_2 is an almost white powder

that is insoluble in most acids, although it can be dissolved in sulfuric acid or other acids when a reducing agent is present. The metal is an iron-gray color and it oxidizes rapidly in air, forming a gray crust of oxide. Cerium has the interesting property that, at very low temperatures or when subjected to high pressures, it exhibits a face-centered cubic form, which is diamagnetic and 18% denser than the common form.

Cermets

A composite material made up of ceramic particles (or grains) dispersed in a metal matrix. Particle size is greater than 1 μm , and the volume fraction is over 25% and can go as high as 90%. Bonding between the constituents results from a small amount of mutual or partial solubility. Some systems, however, such as the metal oxides, exhibit poor bonding between phases and require additions to serve as bonding agents. Cermet parts are produced by powder–metallurgy (P/M) techniques. They have a wide range of properties, depending on the composition and relative volumes of the metal and ceramic constituents. Some cermets are also produced by impregnating a porous ceramic structure with a metallic matrix binder. Cermets can also be used in powder form as coatings. The powdered mixture is sprayed through an acetylene flame, and it fuses to the base material.

Although a great variety of cermets have been produced on a small scale, only a few types have significant commercial use. These fall into two main groups: oxide-base and carbide-base cermets. Other important types include the TiC-base cermets, Al_2O_3 -base cermets, and UO_2 cermets specially developed for nuclear reactors.

The most common type of oxide-base cermets contains Al_2O_3 ceramic particles (ranging from 30% to 70% volume fraction) and a chromium or chromium-alloy matrix. In general, oxide-base cermets have specific gravities between 4.5 and 9.0, and tensile strengths ranging from 144 to 268 MPa. Their modulus of elasticity ranges between 0.25 and 0.34 million MPa, and their hardness range is A 70 to 90 on the Rockwell scale. The outstanding characteristic of oxide-base cermets is that the metal or ceramic can be either the particle or the matrix constituent. The 6MgO–94Cr cermets reverse the roles of the oxide and chromium, that is, the magnesium is added to improve the fabrication and performance of the chromium. Chromium is not ductile at room temperature. Adding MgO not only permits press-forging at room temperature but also increases oxidation resistance to five times that of pure chromium. Of the cermets, the oxide-base alloys are probably the simplest to fabricate. Normal P/M or ceramic techniques can be used to form shapes, but these materials can also be machined or forged. The oxide-base cermets are used as a tool material for high-speed cutting of difficult-to-machine materials. Other uses include thermocouple-protection tubes. Molten-metal-processing equipment parts, mechanical seals, gas-turbine flame holders (resistance to flame erosion), and flow control pins (because of Cr– Al_2O_3 's resistance to wetting and erosion by many molten metals and to thermal shock).

There are three major groups of carbide-base cermets: tungsten, chromium, and titanium. Each of these groups is made up of a variety of compositional types or grades. WC cermets contain up to about 30% cobalt as the matrix binder. They are the heaviest type of cermet (specific gravity is 11–15). Their outstanding properties include high rigidity, compressive strength, hardness, and abrasion resistance. Their modulus of elasticity ranges between 0.45 and 0.65 million MPa, and they have a Rockwell hardness of about A90. Structural uses of WC–Co cermets include wire-drawing dies, precision rolls, gauges, and valve parts. Higher-impact grades can be applied where the steels were formally needed to withstand impact loading. Combined with superior abrasion resistance, the higher

impact strength results in die-life improvements as high, in some cases, as 5000%–7000%. Most TiC cermets have nickel or nickel alloys as the metallic matrix, which results in high-temperature resistance. They have relatively low density combined with high stiffness and strength at temperatures above 1204°C. Typical properties are specific gravity, 5.5–7.3; tensile strength, 517–1068 MPa; modulus of elasticity, 0.25–0.38 million MPa; and Rockwell hardness, A 70 to 90. Typical uses are integral turbine wheels, hot-upsetting anvils, hot-spinning tools, thermocouple protection tubes, gas-turbine nozzle vanes and buckets, torch tips, hot-mill-roll guides, valves, and valve seats. CrC cermets contain from 80% to 90% CrC, with the balance being either nickel or nickel alloys. Their tensile strength is about 241 MPa, and they have a tensile modulus of about 0.34–0.39 million MPa. Their Rockwell hardness is about A88. They have superior resistance to oxidation, excellent corrosion resistance, and relatively low density (specific gravity is 7.0). Their high rigidity and abrasion resistance make them suitable for gauges, oil-well check valves, valve liners, spray nozzles, bearing seal rings, and pump rotors.

Other cermets are barium-carbonate–nickel and tungsten–thoria, which are used in higher-power pulse magnetrons. Some proprietary compositions are used as friction materials. In brake applications, they combine the thermal conductivity and toughness of metals with the hardness and refractory properties of ceramics. UO_2 cermets have been developed for use in nuclear reactors. Cermets play an important role in sandwich-plate fuel elements, and the finished element is a siliconized SiC with a core containing UO_2 . Control rods have been fabricated from B_4C -stainless steel and rare earth oxides-stainless steel. Other cermets developed for use in nuclear equipment include Cr– Al_2O_3 cermets, Ni–MgO cermets, and Fe–ZrC cermets. Nonmagnetic compositions can be formulated for use where magnetic materials cannot be tolerated.

Interactions

The reactions taking place between the metallic and ceramic components during fabrication of cermets may be briefly classified and described as follows:

1. Heterogeneous mixtures with no chemical reaction between the components, characterized by a mechanical interlocking of the components without formation of a new phase, no penetration of the metallic component into the ceramic component, and vice versa, and no alteration of either component (e.g., MgO–Ni).
2. Surface reaction resulting in the formation of a new phase as an interfacial layer that is not soluble in the component materials. The thickness of this layer depends on the diffusion rate, temperature, and time of the reaction (e.g., Al_2O_3 –Be).
3. Complete reaction between the components, resulting in the formation of a solid solution characterized by a polyatomic structure of the ceramic and the metallic component (e.g., TiC–Ni).
4. Penetration along grain boundaries without the formation of interfacial layers (e.g., Al_2O_3 –Mo).

Bonding Behavior

One important factor in the selection of metallic and ceramic components in cermets is their bonding behavior. Bonding may be by surface interaction or by bulk interaction. In cermets of the

oxide-metal type, for example, investigators differentiate among three forms of surface interaction: macrowetting, solid wetting, and wetting assisted by direct lattice fit.

Combinations

One distinguishes basically between four different combinations of metal and ceramic components: (1) the formation of continuous interlocking phases of the metallic and ceramic components, (2) the dispersion of the metallic component in the ceramic matrix, (3) the dispersion of the ceramic component in the metallic matrix, and (4) the interaction between the metallic and ceramic components.

Applications

Aside from the high-temperature applications in turbine buckets, nozzle vanes, and impellers for auxiliary power turbines, there is a wide variety of applications for cermets based on various other properties. One of the most successful applications for the TiC-base cermets is in elements of temperature sensing and controlling thermostats where their oxidation resistance together with their low coefficient of thermal expansion as compared with nickel-base alloys are the important properties. Their ability to be welded directly to the alloys is also important.

The TiC-base cermets are also used for bearings and thrust runners in liquid metal pumps, hot flash trimming and hot spinning tools, hot rod mill guides, antifriction and sleeve-type bearings, hot glass pinch jaws, rotary seals for hot gases, oil well valve balls, etc.

The size of the ceramic component varies, depending on the system and application. It can be as coarse as 50–100 μm , as in some type of cermets based on uranium dioxide (UO_2) that are used for nuclear reactor fuel elements, or as fine as 1–2 μm , as in the micrograin type of cemented carbides. It should be noted, technically, all metal-bonded tungsten carbide materials should fall into the category of cermets. However, it has been customary in the cutting tool industry to designate all cobalt-bonded tungsten carbide compositions as cemented carbides. If the ceramic component is even finer and is present in small amounts, the material is considered a dispersion-strengthened material and therefore falls outside the accepted definition of cermets.

Like cemented carbides, cermets contain a metal binder and are produced by powder metallurgy techniques. The metallic binder phase can consist of a variety of elements, alone or in combination, such as nickel, cobalt, iron, chromium, molybdenum, and tungsten; it can also contain other metals, such as stainless steel, superalloys, titanium, zirconium, or some of the lower-melting-point copper or aluminum alloys. The volume fraction of the binder phase depends entirely on the intended properties and end use of the material. It can range anywhere from 15% to 85%, but it is generally kept at the lower half of the scale (e.g., 10%–15%).

Cermets have proven their value in a variety of applications. The most important use of cermets is in cutting tools based on titanium carbide (TiC) or titanium carbonitride (TiC,N). Steel-bonded carbides consisting of 45 vol% TiC are used in wear-resistant parts and in dies and other forming equipment components. Cermets based on UO_2 , as well as those based on uranium carbide (UC), offer potential for advanced fuel elements. Cermets based on zirconium boride (ZrB_2) or silicon carbide (SiC), and others containing alumina (Al_2O_3), silicon dioxide (SiO_2), boron carbide (B_4C), or refractory compounds combined with diamonds, possess unique properties. Several are used commercially in a wide range

of applications, including hot-machining tools, shaft seals, valve components and wear parts, ultrahigh-temperature exposed ducts, nozzles, and other rocket engine components, furnace fixtures and hearth elements, grinding wheels, and diamond-containing drill heads and saw teeth.

Cesium

A chemical element, cesium (symbol Cs) is the heaviest of the alkali metals in group 1. It is a soft, light, very low melting temperature metal. It is the most reactive of the alkali metals and indeed is the most electropositive and the most reactive of all the elements.

Cesium oxidizes easily in the air, ignites at ordinary temperatures, and decomposes water with explosive violence. It can be contained in vacuum, inert gas, or anhydrous liquid hydrocarbons protected from O_2 and air. The specific gravity is 1.903, melting point 28.5°C, and boiling point 670°C. It is used in low-voltage tubes to scavenge the last traces of air. It is usually marketed in the form of its compounds such as cesium nitrate, CsNO_3 , cesium fluoride, CsF , or cesium carbonate, Cs_2CO_3 . In the form of cesium chloride, CsCl , it is used on the filaments of radio tubes to increase sensitivity. It interacts with the thorium of the filament to produce positive ions. In photoelectric cells, CsCl is used for a photosensitive deposit on the cathode, since cesium releases its outer electron under the action of ordinary light, and its color sensitivity is higher than that of other alkali metals. The high-voltage rectifying tube for changing AC to DC has cesium metal coated on the nickel cathode, and has cesium vapor for current carrying. The cesium metal gives off a copious flow of electrons and is continuously renewed from the vapor. Cesium vapor is also used in the infrared signaling lamp as it produces infrared waves without visible light. Cesium salts have been used medicinally as antishock agents after administration of arsenic drugs.

Cesium metal is generally made by thermochemical processes. The carbonate can be reduced by metallic magnesium, or the chloride can be reduced by CaC. Metallic cesium volatile lodges from the reaction mixture and is collected by cooling the vapor.

C-Frame Press

Same as a *gap-frame press*.

CFRP

Carbon Fiber Reinforced Plastics.

C-Glass

A glass with a soda-lime-borosilicate composition that is used for its chemical stability and corrosive environments.

Chafing

(1) Repeated rubbing between two solid bodies that can result in surface damage and/or wear. (2) Local abrasion or sometimes an alternative term for fretting.

Chafing Fatigue

Fatigue initiated in a surface damage by rubbing against another body. See also *fretting*.

Chain

(1) A length of interlinked loops intended to carry tensile loads and, sometimes transmit drive between toothed chain wheels. (2) A string of linked atoms forming, usually, an organic molecule.

Chain Intermittent Weld

A weld made intermittently along the two sides of a joint, for example, a T fillet weld, with the welds on the two sides lying opposite each other. Where the welds on one side lie opposite the gaps on the other the joint is termed a Staggered Intermittent Weld. Contrast with *staggered-intermittent fillet welding*.

Chain Length

In plastics, the length of the stretched linear macromolecule, most often expressed by the number of identical links.

Chain Reaction

Any continuing process occurring in repeating steps where each step initiates the next. The term often refers to nuclear reactions where fission of one atom releases neutrons that cause fission in further atoms and so on.

Chain Transfer Agent

In plastics, a molecule from which an atom, such as hydrogen, may be readily abstracted by a free radical.

Chalcogenide

A binary or ternary compound containing a chalcogen (sulfur, selenium, or tellurium) and a more electropositive element. Ternary molybdenum chalcogenides, $M_x-Mo_6X_8$ where M is a cation and X is a chalcogen, are superconducting materials.

Chalk

A fine-grained limestone, or a soft, earthy form of *calcium carbonate*, $CaCO_3$, composed of finely pulverized marine shells. The natural chalk comes largely from the southern coast of England and the north of France, but high-calcium marbles and limestones are the sources of most U.S. chalk and precipitated calcium carbonate. Chalk is employed in putty, crayons, paints, rubber goods, linoleum, calcimine, and as a mild abrasive in polishes. *Whiting* and *Paris white* are names given to grades of chalk that have been ground and washed for use in paints, inks, and putty. French chalk is a high grade of massive talc cut to shape and used for marking. Chalk should be white, but it may be colored gray or yellowish by impurities. The commercial grades depend on the purity, color, and fineness of the grains. The specific gravity may be as low as 1.8.

Precipitated calcium carbonate is the whitest of the pigment extenders. *Kalite*, of Diamond Alkali Co., is a precipitated calcium carbonate of 39 μm . (1 μm) particle size, and *Suspensol*, *Surfex*, and *Nonferal* are grades with particle sizes from 197 to 394 μm . (5 to 10 μm). *Whitcarb RC*, of Witco Corp., for rubber compounding, is a fine-grained grade, 2.56 μm . (0.065 μm), coated to prevent dusting and for easy dispersion in the rubber. Purecal SC is a similar material. *Limeolith*, *Calcene*, of PPG Industries, and *Kalvan*,

of R.T. Vanderbilt Co., Inc., are precipitated calcium carbonates. A highly purified calcium carbonate for use in medicine as an antacid is *Amitone*.

Chalking

(1) Dry, chalk-like appearance of deposit on the surface of a plastic. (2) The development of loose removable powder at the surface of an organic coating usually caused by weathering.

Chamber Furnace

Powder metallurgy, a batch sintering furnace usually equipped with a retort that can be sealed gas tight.

Chamfer

(1) A beveled surface to eliminate an otherwise sharp corner. (2) A relieved angular cutting edge at a tooth corner.

Chamfer Angle

(1) The angle between a reference surface and the bevel. (2) On a milling contour, the angle between a beveled surface and the axis of the cutter.

Chamfering

Making a sloping surface on the edge of a member. Also called beveling. See also *bevel angle*.

Channeling

(1) The tendency of a grease or viscous oil to form air channels in a bearing or gear system, resulting in an incomplete lubricant film. (2) The tendency of a grease to form a channel by working down in a bearing or distribution system, leaving shoulders to act as a reservoir and seal.

Channeling Pattern

A pattern of lines observed in a scanning electron image of a single-crystal surface caused by preferential penetration, or channeling, of the incident beam between rows of atoms at certain orientations. The pattern provides information on the structure and orientation of the crystal.

Chaplet

Metal support that holds a core in place within a casting mold; molten metal solidifies around a chaplet and fuses it into the finished casting. They are made of similar metal to the casting.

Characteristic

A property of items in a sample or population that when measured, counted, or otherwise observed helps to distinguish between the items.

Characteristic Electron Energy Loss Phenomena

The inelastic scattering of electrons in solids that produces a discrete energy loss determined by the characteristics of the material. The most probable form is due to excitation of valence electrons.

Characteristic Radiation

Electromagnetic radiation of a particular set of wavelengths, produced by and characteristic of a particular element whenever its excitation potential is exceeded. Electromagnetic radiation is emitted as a result of electron transitions between the various energy levels (electron shells) of atoms; the spectrum consists of lines whose wavelengths depend only on the element concerned and the energy levels involved.

Charcoal

An amorphous form of carbon, made by enclosing billets in a retort and exposing them to a red heat for 4 or 5 h. It is also made by covering large heaps of wood with earth and permitting them to burn slowly for about a month. Much charcoal is now produced as a by-product in the distillation of wood, a retort charge of 10 cords of wood yielding an average of 2,650 gal (10,030 L) of pyroligneous liquor, 11,000 lb (4,950 kg) of gas, and 6 tons (5.4 metric tons) of charcoal. *Wood charcoal* is used as a fuel, for making black gunpowder, for carbonizing steel, and for making activated charcoal for filtering and absorbent purposes. *Gunpowder charcoal* is made from alder, willow, or hazelwood. Commercial wood charcoal is usually about 25% of the original weight of the wood and is not pure carbon. The average composition is 95% carbon and 3% ash. It is an excellent fuel, burning with a glow at low temperatures and with a pale-blue flame at high temperatures. Until about 1850, it was used in blast furnaces for melting iron, and it produces a superior iron with less sulfur and phosphorus than when coke is used. *Red charcoal* is an impure charcoal made at a low temperature that retains much oxygen and hydrogen.

Charge

(1) All the solid materials fed into a furnace. (2) Weights of various liquid and solid materials put into a furnace during one feeding cycle. (3) The weight of plastic material used to load a mold at one time or during one cycle. (4) In the case of smelting processes this includes, ore, flux and (solid) fuel but not liquid fuel or air. In the case of secondary production processes, it includes the components being treated and usually any individual support systems but not usually items such as bogies or removable hearths that are a basic part of the furnace. (5) Any process of adding material to a body or system, of imposing a static electric field or of introducing a quantity of electricity to a battery or similar equipment. See also *static charge*.

Charging

(1) For a lap, impregnating the surface with fine abrasive. (2) Placing materials into a furnace.

Charpy Test

An impact test in which a V-notched, keyhole-notched, or U-notched specimen, supported at both ends, is struck behind the notch by a

striker mounted at the lower end of a bar that can swing as a pendulum. The energy that is absorbed in fracture is calculated from the height to which the striker would have risen had there been no specimen and the height to which it actually rises after fracture of the specimen. Contrast with *Izod test* and *impact test*.

Charring

The heating of a reinforced plastic or composite in air to reduce the polymer matrix to ash, allowing the fiber content to be determined by weight.

Chase (Machining)

To make a series of cuts each, except for the first, following in the path of the cut preceding it, as in chasing a thread.

Chase (Plastic)

In plastic part making, an enclosure of any shape, used to shrink-fit parts of a mold cavity in place, prevent spreading or distortion in hobbing, or enclose an assembly of two or more parts in a split cavity block.

Chatter

In machining or grinding, (1) A vibration of the tool, wheel, or workpiece producing a wavy surface on the work and causes noise or local surface damage. More specifically vibration and judder of a cutting tool at the point of metal removal. This causes poor surface quality termed chatter marks. (2) The finish produced by such vibration. (3) In tribology, elastic vibrations resulting from frictional or other instability.

Chatter Marks

Surface imperfections on the work being ground, usually caused by vibrations transferred from the wheel-work interface during grinding.

Check

The intermediate section of a flask that is used between the *cope* and the *drag* when molding a shape that requires more than one parting plane.

Checked Edges

Sawtooth edges seen after hot rolling and/or cold rolling.

Checkers

In a chamber associated with a metallurgical furnace, bricks stacked openly so that heat may be absorbed from the combustion products and later transferred to incoming air when the direction of flow is reversed.

Checking

The development of slight breaks in a coating that do not penetrate to the underlying surface. See also *checks* (1) and *craze cracking*.

Checks

(1) Numerous, very fine cracks in a coating or at the surface of a metal part. Checks may appear during processing or during service and are most often associated with thermal treatment or thermal cycling. (2) The shallow surface cracking, often extensive is the result of thermal shock resulting from the stresses associated with temperature transients. Also called check marks, *checking*, or *heat checks*. (3) Minute cracks in the surface of a casting caused by unequal expansion or contraction during cooling. (4) Cracks in a die impression corner, generally due to forging strains or pressure, localized at some relatively sharp corner. Die blocks too hard for the depth of the die impression have a tendency to check or develop cracks in impression corners. (5) A series of small cracks resulting from thermal fatigue of hot forging dies.

Cheesecloth

A thin, coarse-woven cotton fabric of plain weave, 40–32 count, and of coarse yarns. It was originally used for wrapping cheese, but is now employed for wrapping, lining, interlining, filtering, as a polishing cloth, and as a backing for lining and wrapping papers. The cloth is not sized and may be either bleached or unbleached. It comes usually 36 in. (0.91 m) wide. The grade known as *beef cloth*, originally used for wrapping meats, is also the preferred grade for polishing enameled parts. It is made of No. 22 yarn or finer. For covering meats the packing plants now use a heavily napped knitted fabric known as *stockinett*. It is made either as a flat fabric or in seamless tube form, and it is also used for covering inking and oiling rolls in machinery. Later grades of cheesecloth, with very open weave, known as *gauze*, are used for surgical dressings and for backings for paper and maps. *Baling paper* is made by coating cheesecloth with asphalt and pasting to one side of heavy craft or Manila paper. *Cable paper*, for wrapping cables, is sometimes made in the same way but with insulating varnish instead of asphalt. *Buckram* is a coarse, plain-woven open fabric similar to cheesecloth but heavier and highly sized with water-resistant resins. It is usually made of cotton, but may be of linen, and is white or in plain colors. It is used as a stiffening material, for bookbindings, inner soles, and interlinings. *Cotton bunting* is a thin, soft, flimsy fabric of finer yarn and tighter weave than cheesecloth, used for flags, industrial linings and declarations. It is dyed in solid colors or printed. But usually, the word *bunting* alone refers to a more durable, and nonfading, lightweight, worsted fabric in plain weave.

Chelant/Chelate Corrosion Attack

Corrosion on the water side of steam generating tubes resulting from excessive quantities, generally or locally, of chelating agent in the same manner as caustic attack. Corrosion may also be promoted by excess oxygen, turbulence, and high water velocities.

Chelate

(1) Five- or six-membered ring formation based on intramolecular attraction of H, O, or N atoms. (2) A molecular structure in which a heterocyclic ring can be formed by the unshared electrons of neighboring atoms. (3) A *coordination compound* in which a heterocyclic ring is formed by a metal down to two atoms of the associated *ligand*. See also *complexation*.

Chelating Agent

(1) An organic compound in which atoms form more than one coordinate bond with metals and solution. (2) A substance used in metal

finishing to control or eliminate certain metallic ions present in undesirable quantities. Same as *chelant*.

Chelating Agents

Also called chelants and used to capture undesirable metal ions in water solutions, affect their chemical reactivity, dissolve metal compounds, increase color intensity in organic dyes, treat waters and organic acids, and preserve quality of food products and pharmaceuticals. Three major classes of organic chelants are *aminopolycarboxylic acids (APCAs)*, *phosphonic acids*, and *polycarboxylic acids*. The polycarboxylic acids include *citrates*, *gluconates*, *polycrylates*, and *polyaspartates*. APCAs are stable at high temperatures and pH values, have a strong attraction for metals, and are not too costly. Their chelate stability surpasses that of the other two classes; they are useful in most industrial applications including metal cleaning, gas treatment by sulfur removal, and pulp and wood processing. The phosphonic acids are more costly but are stable over a wide range of temperature and pH values. They are used to treat waters to inhibit corrosion of storage vessels and for metals and plastics processing. The polycarboxylic acids are weak and less stable, but inexpensive and useful for alkaline-earth and hardness-ion control. In the United States, the major chelant producers are Dow Chemical, Akzo-Nobel, and BASF. Phosphates have been severely restricted for environmental reasons, especially in household detergents. *EDTA* has been implicated for raising metal concentrations in rivers by remobilizing metals in sludge. *Citrates*, which are biodegradable, are being used increasingly as substitutes for phosphates in liquid laundry detergents. *NTA*, a biodegradable member of EDTA, has largely replaced phosphates and detergents in Canada but is listed as a suspected carcinogen in the United States. *Zeolites*, though not chelants, serve as phosphate substitutes in detergents but are not as effective in removing magnesium. *Polyelectrolytes*, lightweight polymers of *acrylic acid* and *maleic anhydride*, reduce scale formation by dispersing calcium as fine particles.

Chelation

A chemical process involving formation of a heterocyclic ring compound that contains at least one metal cation or hydrogen ion in the ring.

Chemical Adsorption

See *chemisorption*.

Chemical Attack

An imprecise term implying any adverse effect resulting from a chemical reaction between a material and its environment. Such effects include chemical dissolution or combination with a component of the environment resulting in oxidation, scaling, rusting, pitting, etc., the term usually does not include damage mechanisms with a nonchemical component such as stress corrosion cracking or corrosion fatigue cracking.

Chemical Blowing Agent

In processing of plastics, an agent that readily decomposes to produce a gas.

C

Chemical Bonding

The joining together of atoms to form molecules. See also *molecule* and *interatomic bonding*.

Chemical Cleaning

The removal of surface films, rust and other contamination by the immersion in, or application of, appropriate chemicals.

Chemical Compound

A substance that comprises two or more elements joined in an interatomic bond in fixed weight ratios.

Chemical Conversion Coating

A protective or decorative nonmetallic coating produced *in situ* by chemical reaction of a metal with a chosen environment. It is often used to prepare the surface prior to the application of an organic coating.

Chemical Decomposition

The separating of a compound into its constituents.

Chemical Deposition

(1) The precipitation or plating-out of a metal from solutions of its salts through the introduction of another metal or reagent to the solution. (2) The deposition of a coating on an immersed surface by a chemical reaction between constituents of the solution or between the constituents in the surface.

Chemical Equivalent (of an Element)

The atomic weight divided by the valence.

Chemical Etching

The dissolution of the material of a surface by subjecting it to the corrosive action of an acid or an alkali.

Chemical Flux Cutting

An oxygen cutting process in which metals are severed using a chemical flux to facilitate cutting.

Chemical Indicators

Dyestuffs that have one color in acid solutions and a different color in basic or alkaline solutions. They are used to indicate the relative acidity of chemical solutions, as the different materials have different ranges of action on the acidity scale. The materials are mostly weak acids, but some are weak bases. The best known is *litmus*, which is red below a pH of 4.5 and blue above a pH of 8.3 and is used to test strong acids or alkalis. It is a natural dye prepared from several varieties of lichen, *Variolaria*, chiefly *Rocella tinctoria*, by allowing them to ferment in the presence of ammonia and potassium carbonate. When fermented, the mass has a blue-color and is mixed with chalk and made into tablets of papers. It is used also as a textile dye, wood stain, and food colorant.

Some coal-tar indicators are *malachite green*, which is yellow below a pH of 0.5 and green above 1.5; *phenolphthalein*, which is colorless below 8.3 and magenta above 10.0; and *methyl red*, which is red below 4.4 and yellow above 6.0. A universal indicator is a mixture of a number of indicators that gives a whole range of color changes, thereby indicating the entire pH range. But such indicators must be compared with a standard to determine the pH value.

The change in color is caused by a slight rearrangement of the atoms of the molecule. Some of the indicators, such as *thymol blue*, exhibit two color changes at different acidity ranges because of the presence of more than one chromophore arrangement of atoms. These can thus be used to indicate two separate ranges on the pH scale. Test papers are strips of absorbent paper that have been saturated with an indicator and dried. They are used for testing for acidic or basic solutions, and not for accurate determination of acidity range or hydrogen-ion concentration, such as is possible with direct use of the indicators. *Litmus paper* is used for acidity testing. Starch-iodide paper is paper dipped in starch paste containing potassium iodide. It is used to test for halogens and oxidizing agents such as hydrogen peroxide.

Chemical Lead

Lead, usually as sheet, high purity, 99.9% or better, for chemical reaction vessels or linings.

Chemical Machining

Removing metal stock by controlled selective chemical dissolution.

Chemical Metallurgy

See *process metallurgy*.

Chemical Milled Parts

Chemical milling is the process of producing metal parts to predetermined dimensions by chemical removal of metal from the surface. It is a machining process in which metal is formed into intricate shapes by masking certain portions and then etching away the unwanted material.

Acid or alkaline, pickling, or etching baths have been formulated to remove metal uniformly from surfaces without excessive etching, roughening, or grain boundary attack. Simple immersion of a metal part will result in uniform removal from all surfaces exposed to the chemical solution. Selective milling is accomplished by use of a mask to protect the areas where no metal is to be removed. By such means optimum strength per unit of construction weight is achieved. Nonuniform milling can be done by the protective masking procedure or by programmed withdrawal of the part from the milling bath. Complex milling is done by multiple masking and milling or withdrawal steps.

Versatility Offered

The aircraft industry, as an example, utilizes production chemical milling for weight reduction of large parts by means of precise etching. The process is the most economical means of removal of metal from large areas, nonplanar surfaces, or complex shapes. A further advantage is that metal is just as easily removed from fully hardened as from annealed parts. The advantages of chemical milling result from the fact that metal removal takes place on

all surfaces contacted by the etching solution. The solution will easily mill inside and reentrant surfaces as well as thin metal parts or parts that are multiple racked. The method does not require elaborate fixturing or precision setups, and parts are just as easily milled after forming as in the flat. Job lots and salvage are treated, as well as production runs.

Maximum weight reduction is possible through a process of masking, milling, measuring, and remilling with steps repeated as necessary. Planned processing is the key to production of integrally stiffened structures milled so that optimum support of stresses is attained without the use of stiffening by attachment, welding, or riveting.

A level of ability comparable to that required for electroplating is necessary to produce chemically milled parts. Planned processing, solution control, and developed skill in masking and handling of the work are requisite to success. Periods to train personnel, however, are relatively short as compared to training for other precision metal-removal processes.

Tooling requirements are simple. Chemicals, tanks, racks, templates, a hoist, hangers, and a few special hand and measuring tools are required.

Although chemical milling skill can be acquired without extensive training, it is not feasible to expect to produce the extremes of complexity and precision without an accumulation of considerable experience. However, a number of organizations are available that will produce engineering quality parts on a job shop basis. The processes are well established, commercially, either in or out of the plant.

Specific Etchants Needed

It is anticipated that any metal or alloy can be chemically milled. On the other hand, it does take time to develop a specific process and only those metals can be milled for which an etchant has been developed, tested, and made available. Aluminum alloys have been milled for many years. Steel, stainless steel, nickel alloys, titanium alloys, and superalloys have been milled commercially and a great number of other metals and alloys have been milled experimentally or on a small commercial scale.

It is advantageous to be able to mill a metal without changing the heat-treated condition or temper, as can be done chemically. Defective or nonhomogeneous metal, however, can respond unfavorably. Porous castings will develop holes during milling and mechanically or thermally stressed parts will change in shape as stressed metal is removed. Good-quality metal and controlled heat treating, tempering, and stress relieving are essential to uniformity and reproducibility.

Process Characteristics

Almost any metal size or shape can be milled; limitations are imposed only by extreme conditions such as complex shapes with inverted pockets that will trap gases released during milling, or very thin metal foil that is too flimsy to handle. Shapes can be milled that are completely impractical to machine. For example, the inside of a bent pipe could easily be reduced in section by chemical removal of metal. This possibility is used to advantage to reduce weight on many difficult-to-machine areas such as webs of forgings or walls of tubing. Thin sections are produced by milling when alternate machining methods are excessively costly and the optimum in design demands thin metal shapes that are beyond commercial casting, drawing, or extruding capabilities.

Surface roughness is often reduced during milling from a rough-machined, cast, or forged surface to a semimatte finish. The milled finish may vary from about 30 to 250 $\mu\text{in.}$, depending on the original finish, the alloy, and the etchant. In some instances, the production of an attractive finish reduces finishing steps and is a cost advantage. So-called etching that takes place during milling often causes a brightened finish and etchants have been developed that do not result in a loss of mechanical properties.

Complement Machining

Chemical milling has flourished in the aircraft industry where paring away of every ounce of weight is important. It has spread to instrument industries where weight or balance of working parts is important to the forces required to initiate and sustain motion. It has also become a factor in the design of modern weight-limited portable equipment.

A realistic appraisal of the limitations and advantages of the process is essential to optimum designs. The best designs result from complementing mechanical, thermal, and chemical processes. Chemical milling is not a substitute for mechanical methods but, rather, is more likely as an alternative where machining is difficult or economically unfeasible. It does not compete with low-cost, mass production mechanical methods but, rather, is successful where other methods are limited due to the configuration of the part.

Tolerances

It is good design practice to allow a complex shape to be manufactured by the most economical combinations of mechanical and chemical means. To allow this, print tolerances must reflect allowances that are necessary to apply chemical milling. Chemical milling will produce less well-defined cuts, radii, and surface finishes. The tolerance of a milled cut will vary with the depth of the cut. For 2.5 mm cut, a tolerance in depth of cut of ± 0.10 mm is commercial. This must be allowed in addition to the original sheet tolerance. Line definition (deviation from a straight line) is usually ± 0.8 mm. Unmilled lands between two milled areas should be 0.004 mm minimum. Greater precision can be had at a premium price.

In general, milling rates are about 0.0004 mm/s and depth of cut is controlled by the immersion time. Cuts up to 12.7 mm are not unrealistic although costs should be investigated before designs are made that are dependent on deep cuts.

Limitations

There are limitations to the process. Deep cuts on opposite sides of a part should not be taken simultaneously. One side can be milled at a time but it is less costly to design for one cut rather than two. Complex parts can be made by step milling or by programmed removal of parts to produce tapers. In general, step milling is less expensive and more reliable. Chemical milling engineers should be consulted relative to the feasibility and cost of complex design. Very close tolerance parts can be produced by milling, checking, masking, and re-milling but such a multiple-step process could be more costly than machining.

Chemical Polishing

A process that produces a polished surface by the action of a chemical etching solution. The etching solution is compounded so that peaks in the topography of the surface are dissolved preferentially.

C

The chemical dissolution is performed without the assistance of abrasives or an external electric current.

Chemical Potential

In a thermodynamic system of several constituents, the rate of change of the Gibbs function of the system with respect to the change in the number of moles of a particular constituent.

Chemical Vapor Deposited (CVD) Carbon

Carbon deposited on a substrate by pyrolysis of a hydrocarbon, such as methane.

Chemical Vapor Deposition (CVD)

(1) A coating process, similar to gas carburizing and carbonitriding, whereby a reactant atmosphere gas is fed into a processing chamber where it decomposes at the surface of the workpiece, liberating one material for either absorption by, or accumulation on, the workpiece. A second material is liberated in gas form and is removed from the processing chamber, along with excess atmosphere gas. (2) Process used in manufacture of several composite reinforcements, especially boron and silicon carbide, in which desired reinforcement material is deposited from vapor phase onto a continuous core, for example, boron on tungsten wire (core).

Chemical Wear

See *corrosive wear*.

Chemically Precipitated Powder

A metal powder that is produced as a fine precipitate by chemical displacement.

Chemically Strengthened

Glass that has been ion-exchanged to produce a compressive stress layer at the treated surface.

Chemisorption

(1) The taking up of a liquid or gas or of a dissolved substance, only one molecular layer in thickness, wherein a new chemical compound or bond is formed between the sorbent surface atoms and those of the sorbate. (2) The binding of an adsorbate to the surface of a solid by forces whose energy levels approximate those of a chemical bond. Contrast with *physisorption*.

Chevron Pattern

A fractographic pattern of radial marks (shear ledges) that look like nested letters “V”; sometimes called a herringbone pattern. Chevron patterns are typically found on brittle fracture surfaces in parts whose widths are considerably greater than their thicknesses. The points of the chevrons can be traced back to the fracture origin.

Chill

(1) A metal or graphite insert embedded in the surface of a casting sand mold or core or placed in a mold cavity to increase the cooling

rate at that point. (2) White iron occurring on a gray or ductile iron casting, such as the chill in the wedge test. See also *chilled iron*. Compare with *inverse chill*.

Chill Casting

Any casting technique which promotes rapid cooling when particularly casting into metal molds. See also *splat casting*.

Chill Coating

In casting, applying a coating to a *chill* that forms part of the mold cavity so that the metal does not adhere to it, or applying a special coating to the sand surface of the mold that causes the iron to undercool.

Chill Crystals

The first fine crystals formed on the faces of castings as a result of solidification initiating at the large number of nuclei that result from the local undercooling, i.e., chilling, by the cold mold surface.

Chill Mark

A wrinkled surface condition on glassware resulting from uneven cooling in the forming process.

Chill Plate (in Welding)

A substantial piece of material held in good thermal contact with a more flimsy component to protect that component from overheating during welding.

Chill Ring

See preferred term *backing ring*.

Chill Roll

A cored roll, usually temperature controlled by circulating water, that cools the web before winding. For chill roll plastic (cast) film, the surface of the roll is highly polished. In extrusion coating, either a polished or matte surface may be used, depending on the surface desired on the finish coating.

Chill Roll Extrusion

The extruded plastic film is cooled while being drawn around two or more highly polished chill rolls cored for water cooling for exact temperature control. Also called cast film extrusion.

Chill Time

See preferred term *quenched time*.

Chilled Iron

Cast iron that is poured into a metal mold or against a mold insert so as to cause the rapid solidification that often tends to produce a white iron structure in the casting.

Chin (Ceramics and Glasses)

- (1) Area along an edge or corner where the material has broken off.
- (2) An imperfection due to breakage of a small fragment out of an otherwise regular surface.

China

A glazed or unglazed vitreous ceramic whiteware use for nontechnical purposes. This term designates such products as dinnerware, sanitary ware, and artware when they are vitreous.

Chinese-Script Eutectic

A configuration of eutectic constituents, found particularly in some cast alloys of aluminum containing iron and silicon and in magnesium alloys containing silicon, that resembles the characters in Chinese script.

Chip

- (1) Small metal particles cut away during machining.
- (2) A integrated circuit comprising a series of interconnected electronic devices such as transistors, resistors, etc. A large number of chips are formed together on a wafer, that is, a sheet of, usually, silicon.

Chip Breaker

- (1) Notch or groove in the face of a tool parallel to the cutting edge, designed to break the continuity of the chip.
- (2) A step formed by an adjustable component clamped to the face of the cutting tool.
- (3) Features in the microstructure, particularly inclusions, which provide a plane of weakness causing breakup of the material removed during machining operations. See *free machining*.
- (4) Details on the profile of a machining tool that promote material removal as chips rather than continuous strands.

Chipping

- (1) Removing seams and other surface imperfections in metals manually with a chisel or gouge, or by a continuous machine, before further processing.
- (2) Similarly, removing excessive metal.

Chips (Composites)

Minor damage to a protruded surface of a composite material that removes material but does not cause a crack or craze.

Chips (Metals)

Pieces of material removed from a workpiece by cutting tools or by an abrasive medium.

Chisel Steel

Any steel used for chisels and similar tools. Handheld carpenter chisels are typically high carbon steels, larger chisels for more onerous duty may be of various low alloy steels. They will be hardened and tempered as appropriate to the work. See *steel*.

Chitin

A cellulose-like polysaccharide, it holds together the shells of such crustaceans as shrimp, crab, and lobster; and it is also found in insects, mollusks, and even some mushrooms. It ranks after cellulose as nature's most abundant polymer. Deacylation of chitin, a poly-*N*-acetyl glucose amine, yields *chitosan*, a cationic electrolyte that finds occasional use as a replacement for some cellulosic materials. Chitosan may serve as a flocculant and wastewater treatment, thickener or extender in foods, coagulant for healing wounds in medicine, and coating for moisture proof films. Chitin is insoluble in most solvents, whereas chitosan, although insoluble in water, organic solvents, and solutions above pH 6.5, it is soluble in most organic acids and dilute mineral acids. For removing heavy metals from wastewater, Manville Corp, immobilizes bacteria on diatomaceous earth and then coats the complex with chitosan; the bacteria degrade organic material, and the chitosan absorbs heavy metals, such as nickel, zinc, chromium, and arsenic.

Chloride of Lime

A white powder, a *calcium chloride hypochlorite*, having a strong chlorite order. It decomposes easily in water and is used as a source of chlorine for cleaning and bleaching. It is produced by passing chlorine gas through slaked lime. Chloride of lime, or *chlorinated lime*, is also known as *bleaching powder*, although commercial bleaching powder may also be a mixture of calcium chloride and calcium hypochlorite, and the term *bleach* is used for many chlorinated compounds.

Chlorinated Hydrocarbons

A large group of materials that have been used as solvents for oils and fats, for metal degreasing, dry cleaning of textiles, as refrigerants, in insecticides and fire extinguishers, and as foam-blowing agents. They range from the gaseous methyl chloride to the solid *hexachloroethane*, with most of them liquid. The increase in the number of chlorine atoms increases the specific gravity, boiling point, and some other properties. They may be divided into four groups: the methane group, including methyl chloride, chloroform, and carbon tetrachloride; the ethylene group, including dichloroethylene; the ethane group, including ethyl chloride and dichloroethane; and the propane group. All of these are toxic, and the fumes are injurious when breathed or absorbed through the skin. Some decompose in light and heat to form more toxic compounds. Some are very inflammable, while others do not support combustion. In general, they are corrosive to metals. Some have been implicated in the depletion of ozone in the stratosphere.

Chloroform, or trichloromethane or methenyl trichloride, is a liquid of composition CHCl_3 . Used industrially as a solvent for greases and resins and in medicine as an anesthetic. It decomposes easily in the presence of light to form phosgene, and a small amount of ethyl alcohol is added to prevent decomposition. Ethyl chloride is a gas used in making ethyl fuel for gasoline, as a local anesthetic in dentistry, as a catalyst in rubber and plastics processing, and as a refrigerant and household refrigerators. It is marketed compressed into cylinders as a colorless liquid. Its disadvantage as a refrigerant is that it is highly inflammable, and there is no simple test for leaks. *Methyl chloride* is a gas which is compressed into cylinders as a colorless liquid. Methyl chloride is one of the simplest and cheapest chemicals for methylation. In water solution, it is a good solvent. It is also used as a catalyst in rubber processing, as a restraining gas in high-heat thermometers,

and as a refrigerant. *Monochlorobenzene* is a colorless liquid, not soluble in water. It is used as a solvent for lacquers and resins, as a heat-transfer medium, and for making other chemicals. *Trichlorocumene*, or *isopropyl trichlorobenzene*, is valued as a hydraulic fluid and dielectric fluid because of its high dielectric strength, low solubility in water, and resistance to oxidation. It is a colorless liquid. *Halane*, used in processing textiles and paper, is a white powder containing 66% available chlorine.

Chlorinated Lubricant

A lubricant containing a chlorine compound that reacts with a rubbing surface at elevated temperatures to protect it from sliding damage. See also *extreme-pressure lubricant*, *sulfochlorinated lubricant*, and *sulfurized lubricant*.

Chlorinated Polyether

Chlorinated polyether is a thermoplastic resin used in the manufacture of process equipment. Chemically, it is a chlorinated polyether of high molecular weight, crystalline in character, and is extremely resistant to thermal degradation at molding and extrusion temperatures. It possesses a unique combination of mechanical, electrical, and chemical-resistant properties, and can be molded in conventional injection and extrusion equipment.

Properties

Chlorinated polyether provides a balance of properties to meet severe operating requirements. It is second only to the fluorocarbons in chemical and heat resistance and is suitable for high-temperature corrosion service.

Mechanical Properties

A major difference between chlorinated polyether and other thermoplastics is its ability to maintain its mechanical strength properties at elevated temperatures. Heat distortion temperatures are above those usually found in thermoplastics and dimensional stability is exceptional even under the adverse conditions found in chemical plant operations. Resistance to creep is significantly high and in sharp contrast to the lower values of other corrosion-resistant thermoplastics. Water absorption is negligible, assuring no change in molded shapes between wet and dry environments.

Chemical Properties

Chlorinated polyether offers resistance to more than 300 chemicals and chemical reagents, at temperatures up to 121°C and higher, depending on environmental conditions. It has a spectrum of corrosion resistance second only to certain of the fluorocarbons.

In steel construction of chemical processing equipment, chlorinated polyether liners or coatings on steel substrates provide the combination of protection against corrosion plus structural strength of metal.

Electrical Properties

Along with the mechanical capabilities and chemical resistance, chlorinated polyether has good dielectric properties. Loss factors are somewhat higher than those of polystyrenes, fluorocarbons,

and polyethylenes, but are lower than many other thermoplastics. Dielectric strength is high and electrical values show a high degree of consistency over a range of frequencies and temperatures.

Fabrication

The material is available as a molding powder for injection-molding and extrusion applications. It can also be obtained in stock shapes such as sheet, rods, tubes, or pipe, and blocks for use in lining tanks and other equipment, and for machining gears, plugs, etc. In the form of a finely divided powder, it is used in a variety of different coating processes.

The material can be injection-molded by conventional procedures and equipment. Molding cycles are comparable to those of other thermoplastics. Rods, sheet, tubes, pipe, blocks, and wire coatings can be readily extruded on conventional equipment and by normal production techniques. Parts can be machined from blocks, rods, and tubes on conventional metalworking equipment.

Sheet can be used to convert carbon steel tanks into vessels capable of handling highly corrosive liquids at elevated temperatures. Using a conventional adhesive system and hot gas welding, sheet can be adhered to sandblasted metal surfaces.

Coatings of a finely divided powder can be applied by several coating processes and offer chemical processors an effective and economical means for corrosion control. Using the fluidized bed process, pretreated, preheated metal parts are dipped in an air-suspended bed of finely divided powder to produce coatings, which after baking are tough, pinhole free and highly resistant to abrasion and chemical attack. Parts clad by this process are protected against corrosion both internally and externally.

Uses

Complete anticorrosive systems are available with chlorinated polyether, and lined or coated components, including pipe and fittings, tanks and processing vessels, valves, pumps, and meters.

Rigid uniform pipe extruded from solid material is available in sizes ranging from 12.7 to 50.8 mm in either Schedule 40 or 80, and in lengths up to 6 m. This pipe can be used with injection-molded fittings with socket or threaded connections.

Lined tanks and vessels are useful in obtaining maximum corrosion and abrasion resistance in a broad range of chemical exposure conditions. Storage tanks, as well as processing vessels protected with this impervious barrier, offer a reasonably priced solution to many processing requirements.

A number of valve constructions can be readily obtained from leading valve manufacturers. Solid injection-molded ball valves, coated diaphragm, and plug valves are among the variety available. Also available are diaphragm valves with solid chlorinated polyether bodies.

Chlorinated Polyethylene

This family of elastomers is produced by the random chlorination of high-density polyethylene. Because of the high degree of chemical saturation of the polymer chain, the most desirable properties are obtained by cross-linking with the use of peroxides or by radiation. Sulfur donor cure systems are available that produce vulcanizates with only minor performance losses compared to that of peroxide cures. However, the free radical cross-linking by means of peroxides is most commonly used and permits easy and safe processing, with outstanding shelf stability and optimum cured properties.

Chlorinated polyethylene elastomers are used in automotive hose applications, premium hydraulic hose, chemical hose, tubing, belting, sheet packing, foams, wire and cable, and in a variety of molded products. Properties include excellent ozone and weather resistance, heat resistance to 149°C (to 177°C in many types of oil), dynamic flexing resistance, and good abrasion resistance.

Chlorinated Rubber

An ivory-colored or white powder produced by the reaction of chlorine and rubber. It contains about 67% by weight of rubber, although it is a mixture of two products, one having a CH₂ linkage instead of a CHCl. Chlorinated rubber is used in acid-resistant and corrosion-resistant paints, in adhesives, and in plastics.

The uncompounded film is brittle, and for paints chlorinated rubber is plasticized to produce a hard, tough, adhesive coating, resistant to oils, acids, and alkalis. It is soluble in hydrocarbons, carbon tetrachloride, and esters, but insoluble in water. The unplasticized material has a high dielectric strength, up to 2300 V/mil (90.6 × 10⁶ V/m). *Pliofilm*, of Goodyear Tire and Rubber Company, is a rubber hydrochloride made by saturating the rubber molecule with hydrochloric acid. It is made into transparent sheet wrapping material which heat-seals at 221°F–266°F (105°C–130°C), or is used as a coating material for fabrics and paper. It gives a tough, flexible, water-resistant film. *Betacote 95* is a maintenance paint for chemical processing plants which is based on chlorinated rubber. It adheres to metals, cements, and wood and is rapid-drying; the coating is resistant to acids, alkalis, and solvents.

Chlorination

(1) Roasting ore in contact with chlorine or a chloride salt to produce chlorides. (2) Removing dissolved gases and entrapped oxides by passing chlorine gas through molten metal such as aluminum and magnesium. (3) The most common is chlorination of water to kill bacteria. (4) In a metallurgical context, chlorine may be injected into molten magnesium as a deoxidizing and degassing agent.

Chlorine

An elementary material, symbol Cl, which at ordinary temperatures is a gas. It occurs in nature in great abundance and combinations, and in such compounds as common salt. A yellowish-green gas, it has a powerful suffocating odor and is strongly corrosive to organic tissues and to metals. During World War I, it was used as a poison gas under the name *Bertholite*. An important use for liquid chlorine is for bleaching textiles and paper pulp, but is also used for the manufacture of many chemicals. It is a primary raw material for chlorinated hydrocarbons and for such inorganic chemicals as titanium tetrachloride. Chlorine is used extensively for treating potable, process, and wastewaters. Its use as a biocide has declined due to toxicological and safety issues. A key issue is the chlorinated organics, such as *trihalomethanes* (THMs), that form when chlorine reacts with organics and water. One alternative to chlorine biocides for process waters is FMC Corp.'s *tetra alkyl phosphonium chloride*, a strong biocide containing a surface-active agent that cleans surfaces fouled by biofilm. Use of chlorine in fluorocarbons has decreased as chlorofluorocarbons have been replaced with non-ozone-depleting compounds. Its use in *chlorofluorocarbons*, such as CFC-11 and CFC-12, is decreasing, as these are replaced with more environmentally acceptable refrigerants. Chlorine's used in bleach also has declined. For bleaching, it has been widely employed in the form of compounds easily broken up. The other two oxides of chlorine

are also unstable. *Chlorine monoxide*, or *hypochlorous anhydride*, Cl₂O, is a highly explosive gas. *Chlorine heptoxide*, or *perchloric anhydride*, Cl₂O₇, is an explosive liquid. The *chlorinating agents*, therefore, are largely limited to the more stable compounds. Dry chlorines are used in cleansing powders and for detinning steel, where the by-product is tin tetrachloride.

Chloride may be made by the electrolysis of common salt. The gas is an irritant and not a cumulative poison, but breathing large amounts destroys the tissues. Commercial chlorine is produced in making caustic soda, by treatment of salt with nitric acid, and as a by-product in the production of magnesium metal from seawater or brines. The chlorine yield is from 1.8 to 2.7 times the weight of the magnesium produced.

Chlorine Extraction

Removal of phases by formation of a volatile chloride. See also *extraction*.

Chlorofluorocarbon Plastics

Plastics based on polymers made with monomers composed of chlorine, fluorine, and carbon only.

Chlorofluorohydrocarbon Plastics

Plastics based on polymers made with monomers composed of chlorine, fluorine, hydrogen, and carbon only.

Chlorosulfonated Polyethylene

This material, more commonly known as *Hypalon*, can be compounded to have an excellent combination of properties including virtually total resistance to ozone and excellent resistance to abrasion, weather, heat, flame, oxidizing chemicals, and crack growth. In addition, the material has low moisture absorption, good dielectric properties, and can be made in a wide range of colors because it does not require carbon black for reinforcement. Resistance to oil is similar to that of neoprene. Low-temperature flexibility is fair at –40°C.

The material is made by reacting polyethylene with chlorine and SO₂ to yield chlorosulfonated polyethylene. The reaction changes the thermoplastic polyethylene into a synthetic elastomer that can be compounded and vulcanized. The basic polyethylene contributes chemical inertness, resistance to damage by moisture, and good dielectric strength. Inclusion of chlorine in the polymer increases its resistance to flame (makes it self-extinguishing) and contributes to its oil and weather resistance.

Selection

Hypalon is a special-purpose rubber, not particularly recommended for dynamic applications. The elastomer is produced in various types, with generally similar properties. The design engineer can best rely on the rubber formulator to select the appropriate type for a given application, based on the nature of the part, the properties required, the exposure, and the performance necessary for successful use.

In combination with properly selected compounding ingredients, the polymer can be extruded, molded, or calendered. In addition, it can be dissolved to form solutions suitable for protective or decorative coatings.

C

Initially used in pump and tank linings, tubing, and comparable applications where chemical resistance was of prime importance, this synthetic rubber is now finding many uses where its weatherability, its colorability, its heat, ozone, and abrasion resistance, and its electrical properties are of importance. Included are jacketing and insulation for utility distribution cable, control cable for atomic reactors, automotive primary and ignition wire, and linemen's blankets. Among heavy-duty applications are conveyor belts for high-temperature use and industrial rolls exposed to heat, chemicals, or abrasion.

Interior, exterior, and underhood parts for cars and commercial vehicles are an increasingly important area of use. Representative automotive applications are headliners, window seals, spark plug boots, and tractor seat coverings.

Chlorosulfonated polyethylene is used in a variety of mechanical goods, such as V-belts, motor mounts, O-rings, seals, and gaskets, as well as in consumer products like shoe soles and garden hose. It is also used in white sidewalls on automobile tires. In solution, it is used for fluid-applied roofing systems and pool liners, for masonry coatings, and various protective-coating applications. It can also be extruded as a protective and decorative veneer for such products as sealing and glazing strips.

Chord Modulus

The slope of the chord drawn between any two specific points on a *stress-strain curve*. See also *modulus of elasticity*.

Chromadizing

Improved paint adhesion on aluminum or aluminum alloys or magnesium alloys, mainly aircraft skins, by treatment with a solution of chromic acid. Also called chromidizing or chromatizing. Not to be confused with *chromating* or *chromizing*.

Chromate Treatment

A treatment of metal in a solution of a hexavalent chromium compound to produce a *conversion coating* consisting of trivalent and hexavalent chromium compounds.

Chromatic Aberration

A defect in a lens or optical lens system resulting in different focal lengths for radiation of different wavelengths. The dispersive power of a single positive lens focuses light from the blue end of the spectrum at a shorter distance than from the red end. An image produced by such a lens shows color fringes around the border of the image.

Chromating

The development of a metal/chromium conversion coating by immersion in a solution containing chromium compounds. The coating enhances corrosion resistance and improves paint adhesion. Performing a *chromate treatment*.

Chromatogram

In materials characterization, the visual display of the progress of a separation achieved by *chromatography*. A chromatogram shows the response of a chromatographic detector as a function of time.

Chromatography

The separation, especially of closely related compounds, caused by allowing a solution or mixture to seep through an absorbent (such as clay, gel, or paper) such that each **compound** becomes absorbed in a separate, often colored, layer.

Chrome Plating

(1) Producing a chromate conversion coating on magnesium for temporary protection or for a paint base. (2) The solution heat produces the conversion coating. (3) Is widely used where extreme hardness or resistance to corrosion is required. When plated on a highly polished metal, it gives a smooth surface that has no capillary attraction to water or oil, and chromium-plated bearing surfaces can be run without oil. For decorative purposes, chromium plates as thin as 0.0002 in. (0.0006 cm) may be used.

Chromel

(1) A 90Ni–10Cr alloy used in thermocouples. (2) A series of nickel–chromium alloys, some with iron, used for heat-resistant applications. (3) The most well-known that, with Alumel, is widely used for thermocouples.

Chromia

Formula Cr_2O_3 , a compound having many properties and derivatives similar to those of *alumina*. Useful either pure or impure (e.g., as chrome ore) in both basic and high-alumina refractories.

Chromic Acid

A name given to the red, crystalline, strongly acid material of composition CrO_3 known also as *chromium trioxide* or as *chromic anhydride*. It is, in reality, not the acid until dissolved in water, forming a true chromic acid of composition H_2CrO_4 . It is marketed in the form of porous lumps. It is produced by treating sodium or potassium dichromate with sulfuric acid. The dust is irritating and the fumes of the solutions are injurious to the nose and throat because the acid is a powerful oxidizing agent. Chromic acid is used in chromium-plating baths, for etching copper, and electric batteries, and in tanning leather.

Chrome oxide green is a *chromic oxide* in the form of dry powder or ground in oil, used in paints and lacquers and for coloring rubber. It is a bright-green crystalline powder of composition Cr_2O_3 , and insoluble in water. The dry powder has a Cr_2O_3 content of 97% minimum and is 325 mesh. The paste contains 85% pigment and 15% linseed oil. Chrome oxide green is not as bright in color as chrome green but is more permanent.

Chromium

An elementary metal, chromium (symbol Cr) is used in stainless steels, heat-resistant alloys, high-strength alloy steels, electrical-resistance alloys, wear-resistant and decorative electroplating, and, in its compounds, for pigments, chemicals, and refractories. The specific gravity is 6.92, melting point 1510°C , and boiling point 2200°C . The color is silvery white with a bluish tinge. It is an extremely hard metal; the electrodeposited plates have a hardness of 9 Mohs. It is resistant to oxidation, is inert to HNO_3 , but dissolves in HCl and slowly in H_2SO_4 . At temperatures above 816°C , it is subject to intergranular corrosion.

Chromium occurs in nature only in combination. Its chief ore is chromite, from which it is obtained by reduction and electrolysis. It is marketed for use principally in the form of master alloys with iron or copper.

Most pure chromium is used for alloying purposes such as the production of Ni–Cr or other nonferrous alloys where the use of the cheaper ferrochrome grades of metal is not possible. In metallurgical operations such as the production of low-alloy and stainless steels, the chromium is added in the form of ferrochrome, an electric-arc furnace product that is the form in which most chromium is consumed.

Uses

Its bright color and resistance to corrosion make chromium highly desirable for plating plumbing fixtures, automobile radiators and bumpers, and other decorative pieces. Unfortunately, chrome plating is difficult and expensive. It must be done by electrolytic reduction of dichromate in H_2SO_4 solution. It is customary, therefore, to first plate the object with copper, then with nickel, and finally, with chromium.

Alloys

In alloys with iron, nickel, and other metals, chromium has many desirable properties. Chrome steel is hard and strong and resists corrosion to a marked degree. Stainless steel contains roughly 18% chromium and 8% nickel. Some chrome steels can be hardened by heat treatment and find use in cutlery; still others are used in jet engines. Nichrome and chromel consist largely of nickel and chromium; they have low electrical conductivity and resist corrosion, even at red heat, so they are used for heating coils in space heaters, toasters, and similar devices. Other important alloys are Hastelloy C—chromium, molybdenum, tungsten, iron, nickel—used in chemical equipment that is in contact with HCl, oxidizing acids, and hypochlorite. Stellite—cobalt, chromium, nickel, carbon, tungsten (or molybdenum)—noted for its hardness and abrasion resistance at high temperatures, is used for lathes and engine valves, and Inconel—chromium, iron, nickel—is used in heat treating and corrosion-resistant equipment in the chemical industry.

Biological Aspects

Chromium is essential to life. A deficiency (in rats and monkeys) has been shown to impair glucose tolerance, decrease glycogen reserve, and inhibit the utilization of amino acids. It has also been found that inclusion of chromium in the diet of humans sometimes, but not always, improves glucose tolerance.

On the other hand, chromates and dichromates are severe irritants to the skin and mucous membranes, so workers who handle large amounts of these materials must be protected against dusts and mists. Continued breathing of the dusts finally leads to ulceration and perforation of the nasal septum. Contact of cuts or abrasions with chromate may lead to serious ulceration. Even on normal skin, dermatitis frequently results.

Chromium Alloys and Steels

Chromium Copper

A name applied to master alloys of copper with chromium used in the foundry for introducing chromium into nonferrous alloys or to *copper–chromium alloys*, or *chromium copper* alloys, which are

high-copper alloys. A chromium–copper master alloy, *Electromet chromium copper*, contains 8%–11% chromium, 88%–90% copper, and a maximum of 1% iron and 0.50% silicon.

Wrought chromium copper alloys are designated C18200, C18400, and C18500, and contain 0.4%–1.0% chromium. Soft, thus ductile, in the solution-treated condition, these alloys are readily cold-worked and can be subsequently precipitation-hardened. Depending on such treatments, tensile properties range from 35,000 to 70,000 lb/in.² (241 to 483 MPa) ultimate strength, 15,000 to 62,000 lb/in.² (103 to 427 MPa) yield strength, and 15% to 42% in elongation. Electrical conductivity ranges from 40% to 85% that of copper. Chromium copper alloys are used for resistance-welding electrodes, cable connectors and electrical parts.

Cr–Mo Steel

This is any alloy steel containing chromium and molybdenum as key alloying elements. However, the term usually refers specifically to steels in the American Iron and Steel Institute (AISI) 41XX series, which contain only 0.030%–1.20% chromium and 0.08%–0.35% molybdenum. Chromium imparts oxidation and corrosion resistance, hardenability, and high-temperature strength. Molybdenum also increases strength, controls hardenability, and reduces the tendency to temper embrittlement. AISI 4130 steel, which contains 0.30% carbon, and 4140 (0.40%) are probably the most common and can provide tensile strengths well above 1379 MPa. Many other steels have greater chromium and/or molybdenum content, including high-pressure boiler steels, most tool steels, and stainless steels. Croloy 2, which is used for boiler tubes for high-pressure superheated steam, contains 2% chromium and 0.50% max molybdenum, and is for temperatures to 621°C, and Croloy 5, which has 5% chromium and 0.50% max molybdenum, is for temperatures to 649°C and higher pressures as well as Croloy 7, which has 7% chromium and 0.50% molybdenum.

Chromium Steels

Any steel containing chromium as the predominating alloying element may be termed chromium steel, but the name usually refers to the hard, wear-resisting steels that derive the property chiefly from the chromium content. Straight chromium steels refer to low-alloy steels in the AISI 50XX, 51XX, and 61XX series. Chromium combines with the carbon of steel to form a hard CrC, and it restricts graphitization. When other carbide-forming elements are present, double or complex carbides are formed. Chromium refines the structure, provides deep-hardening, increases the elastic limit, and gives a slight red-hardness so that the steels retain their hardness at more elevated temperatures. Chromium steels have great resistance to wear. They also withstand quenching in oil or water without much deformation. Up to about 2% chromium may be included in tool steels to add hardness, wear resistance, and nondeforming qualities. When the chromium is high, the carbon may be much higher than in ordinary steels without making the steel brittle. Steels with 12%–17% chromium and about 2.5% carbon have remarkable wear-resisting qualities and are used for cold-forming dies for hard metals, for broaches, and for rolls. However, chromium narrows the hardening range of steels unless balanced with nickel. Such steels also work-harden rapidly unless modified with other elements. The high-chromium steels are corrosion resistant and heat resistant but are not to be confused with the high-chromium stainless steels that are low in carbon, although the non-nickel 4XX stainless steels are very definitely chromium steels. Thus, the term is indefinite but

C

may be restricted to the high-chromium steels used for dies, and to those with lower chromium used for wear-resistant parts such as ball bearings.

Chromium steels are not especially corrosion resistant unless the chromium content is at least 4%. Plain chromium steels with more than 10% chromium are corrosion resistant even at elevated temperatures and are in the class of stainless steels, but are difficult to weld because of the formation of hard brittle martensite along the weld.

Chromium steels with about 1% chromium are used for gears, shafts, and bearings. One of the most widely used bearing steels is AISI 52100, which contains 1.3%–1.6% chromium. Many other chromium steels have greater chromium content and, often, appreciable amounts of other alloying elements. They are used mainly for applications requiring corrosion, heat, and/or wear resistance.

Cr–V Steels

Alloy steel containing a small amount of chromium and vanadium, the latter having the effect of intensifying the action of the chromium and the manganese in the steel and controlling grain growth. It also aids in formation of carbides, hardening the alloy, and in increasing ductility by the deoxidizing effect.

The amount of vanadium is usually 0.15%–0.25%. These steels are valued where a combination of strength and ductility is desired. They resemble those with chromium alone, with the advantage of the homogenizing influence of the vanadium. A Cr–V steel with 0.92% chromium, 0.20% vanadium, and 0.25% carbon has a tensile strength up to 689 MPa, and when heat-treated has a strength up to 1034 MPa and elongation 16%. Cr–V steels are used for such parts as crankshafts, propeller shafts, and locomotive frames. High-carbon Cr–V steels are the mild-alloy tool steels of high strength, toughness, and fatigue resistance. The chromium content is usually about 0.80%, with 0.20% vanadium, and with carbon up to 1%.

Chromium–Molybdenum Heat-Resistant Steels

Alloy steels containing 0.5%–9% Cr and 0.5%–1.10% Mo with a carbon content usually below 0.20%. The chromium provides improved oxidation and corrosion resistance, and the molybdenum increases strength at elevated temperatures. Chromium–molybdenum steels are widely used in the oil and gas industries and fossil fuel and nuclear power plants.

Chromizing

(1) A surface treatment at elevated temperature, generally carried out in pack, vapor, or salt baths, in which an alloy is formed by the inward diffusion of chromium into the base metal. (2) Usually at elevated temperature, which causes chromium to diffuse into the surface to improve corrosion resistance.

Chuck

A device for holding work or tools on a machine so that the part can be held or rotated during machining or grinding.

Chucking Hog

A projection forged or cast onto a part to act as a positive means of driving or locating the part during machining.

Chute

In powder metallurgy, a feeding trough for powder to pass from a fill hopper to the die cavity and an automatic press.

CIL Flow Test

A method of determining the rheology or flow properties of thermoplastic resins. In this test, the amount of the molten resin that is forced through a specified size orifice per unit of time when a specified variable force is applied gives a relative indication of the flow properties of various resins.

CIP

The acronym for *cold isostatic pressing*.

Circle Grid

A regular pattern of circles, often 2.5 mm (0.1 in.) in diameter, marked on a sheet metal blank.

Circle Grinding

Either *cylindrical grinding* or *internal grinding*; the preferred terms.

Circle Shear

A shearing machine with two rotary disc cutters mounted on parallel shafts driven in unison and equipped with an attachment for cutting circles where the desired piece of material is inside the circle. It cannot be employed to cut circles where the desired material is outside the circle.

Circle-Grid Analysis

The analysis of deformed circles to determine the severity with which a sheet metal blank has been deformed.

Circuit

(1) In filament winding of composites, one complete traverse of a winding band from one arbitrary point along the winding path to another point on a plane through the starting point and perpendicular to the axis. (2) The interconnection of a number of components in one or more closed pairs to perform a desired electrical or electronic function.

Circuit Board

In electronics, a sheet of insulating material laminated to foil that is etched to produce a circuit pattern on one or both sides. Also called printed circuit board or printed wiring board.

Circuit Breaker

A device designed to open and close a circuit by nonautomatic means and to open the circuit automatically on a predetermined overload of current, without injury to itself, when properly applied within its rating.

Circular Electrode

See *resistance welding electrode*.

Circular Field

The magnetic field that (a) surrounds a nonmagnetic conductor of electricity, (b) is completely contained within a magnetic conductor of electricity, or (c) both exists within and surrounds a magnetic conductor. Generally applied to the magnetic field within any magnetic conductor resulting from a current being passed through the part or through a section of the part. Compare with *bipolar field*.

Circular Mill

A measurement used to determine the area of wire. The area of a circle that is one one-thousandth inch in diameter.

Circular Resistance Seam Welding

See preferred term *transverse resistance seam welding*.

Circular-Step Bearing

A flat circular hydrostatic bearing with a central circular recess. See also *step bearing*.

Circumferential ("Circ") Winding

In filament-wound reinforced plastics, a winding with the filaments essentially perpendicular to the axis (90° or level winding).

Circumferential Resistance Seam Welding

See preferred term *transverse resistance seam welding*.

CIS Stereoisomer

In engineering plastics, a stereoisomer in which side chains or side atoms are arranged on the same side of a double bond present in a chain of atoms.

Citric Acid

$C_6H_8O_7$, produced from lemons, limes, and pineapples, is a colorless, odorless, crystalline powder of specific gravity 1.66 and melting point 307°F (153°C). It is also produced by the fermentation of blackstrap molasses. It is used as an acidulant in effervescent salts in medicine, and jams, jellies, and carbonated beverages in the food industry. *Acetyl tributyl citrate* is a vinyl resin plasticizer. It is also used in inks, etching, and as a resist in textile dyeing and printing. It is a good antioxidant and stabilizer for tableau and other fats and greases, but is poorly soluble in fats. Citric acid is also used as a preservative in frozen fruits to prevent discoloration and storage. Its salt, *sodium citrate*, is a water-soluble crystalline powder used in soft drinks to give a nippy saline taste, and it is also used in plating baths. Citric acid is a strong chelant and finds use in regenerating ion-exchange resins, recovering metals and spent baths, decontaminating radioactive materials, and controlling metal-ion catalysis. For example, it can be used to extract metal contaminants from incinerator ash and to treat uranium-contaminated soils.

Civil Transformation

A transformation from one solid phase to another in which the atoms at the advancing interface realign themselves to the new crystal lattice in an uncoordinated manner and without regard for the original grain boundaries.

Clad

The attachment of sheet to a structural framework.

Clad Brazing Sheet

A metal sheet on which one or both sides are clad with brazing filler metal.

Clad Metals

Cladding means the strong, permanent bonding of two or more metals or alloys metallurgically bonded together to combine the characteristic properties of each in composite form. Copper-clad steel, for example, is used to combine the electrical and thermal characteristics of copper with the strength of steel. A great variety of metals and alloys can be combined in two or more layers, and they are available in many forms, including sheet, strip, plate, tubing, wire, and rivets for application in electrical and electronic products, chemical-processing equipment, and decorative trim, including auto trim.

Cladding Processes

In the process a clad metal sheet is made by bonding or welding a thick facing to a slab of base metal; the composite plate is then rolled to the desired thickness. The relative thickness of the layers does not change during rolling. Cladding thickness is usually specified as a percentage of the total thickness, commonly 10%.

Other cladding techniques, including a vacuum brazing process, have been developed. The pack rolling process is still the most widely used, however.

Alloys

Generally speaking, the choice of alloys used in cladding is dictated by end-use requirements such as corrosion, abrasion, or strength.

Cladding supplies a combination of desired properties not found in any one metal. A base metal can be selected for cost or structural properties, and another metal added for surface protection or some special properties such as electrical conductivity. Thickness of the cladding can be made much heavier and more durable than obtainable by electroplating.

Combinations

The following clad materials are in common use:

- *Stainless steel on steel*: Provides corrosion resistance and attractive surface at low cost for food display cases, chemical-processing equipment, sterilizers, and decorative trim.
- *Stainless steel on copper*: Combines surface protection and high thermal conductivity for pots and pans, and for heat exchangers for chemical processes.

- *Copper on aluminum:* Reduces cost of electrical conductors and saves copper on appliance wiring.
- *Copper on steel:* Adds electrical conductivity and corrosion resistance needed in immersion heaters and electrical switch parts; facilitates soldering.
- *Nickel or Monel on steel:* Provides resistance to corrosion and erosion for furnace parts, blowers, chemical equipment, toys, brush ferrules, and many mechanical parts in industrial and business machines; more durable than electroplating.
- *Titanium on steel:* Supplies high-temperature corrosion resistance. Bonding requires a thin sheet of vanadium between titanium and steel.
- *Bronze on copper:* Usually clad on both sides, for current-carrying springs and switch blades; combines good electrical conductivity and good spring properties.
- *Silver on copper:* Provides oxidation resistance to surface of conductors, for high-frequency electrical coils, conductors, and braiding.
- *Silver on bronze or nickel:* Adds current-carrying capacity to low-conductivity spring material; cladding sometimes is in form of stripes or inlays with silver areas serving as built-in electrical contacts.
- *Gold on copper:* Supplies chemical resistance to a low-cost base metal for chemical processing equipment.
- *Gold on nickel or brass:* Adds chemical resistance to a stronger base metal than copper; also used for jewelry, wristbands, and watchcases.

Applications

Gold-filled jewelry has long been made by the cladding process: the surface is gold, the base metal bronze or brass with the cladding thickness usually 5%. The process is used to add corrosion resistance to steel and to add electrical or thermal conductivity, or good bearing properties, to strong metals. One of the first industrial applications was the use of a nickel-clad steel plate for a railroad tank car to transport caustic soda; stainless clad steels are used for food and pharmaceutical equipment. Corrosion-resistant pure aluminum is clad to a strong duralumin base, and many other combinations of metals are widely used in cladding; there is also a technique for cladding titanium to steel for jet engine parts.

Today's coinage uses clad metals as a replacement for rare silver. Dimes and quarters have been minted from composite sheet consisting of a copper core with Cu-Ni facing. The proportion of core and facing used duplicates the weight and electrical conductivity of silver so the composite coins are acceptable in vending machines.

A three-metal composite sole plate for domestic steam irons provides a thin layer of stainless steel on the outside to resist wear and corrosion. A thick core of aluminum contributes thermal conductivity and reduces weight, and a thin zinc layer on the inside aids in bonding the sole plate to the body of the iron during casting.

Clad metals have been applied in nuclear power reactor pressure vessels in submarines as well as in civilian power plants.

Other applications where use of clad is increasing are in such fields as fertilizer, chemicals, mining, food processing, and even seagoing wine tankers.

Producers see a market for clad metal curtain wall building panels, and even stainless clad bus and automobile bumpers.

Aluminum-clad wire for electric coils is copper wire coated with aluminum to prevent deterioration of the enamel insulation caused by copper oxide. Solder-clad aluminum strip, developed by Heraeus

Holding, GmbH, has soft solder adhesive-bonded to both sides and is intended for heat exchangers and other products.

DuPont cladding has been applied by explosive bonding and Bethlehem Lukens just as well by roll bonding. Clad plate includes carbon, alloy, and stainless-steel plate clad with stainless steel, copper or nickel alloys, titanium, tantalum, or zirconium. Clad-plate transition joints are made by DuPont. Other products include *clad wire*, *clad rivets*, and *clad welding tapes*.

Composite tool steel, used for shear blades and die parts, is not a laminated metal. The term refers to bar steel machined along the entire length and having an insert of tool steel welded to the backing of mild steel. Clad steels are available regularly in large sheets and plates. They are clad with nickel, stainless steel, Monel metal, aluminum, or special alloys on one or both sides of the sheet. Where heat and pressure are used in the processing, there is chemical bonding between the metals. For some uses the cladding metal on one side will be 10%–20% of the weight of the sheet. A composite plate having an 18-8 stainless steel cladding to a thickness of 20% on one side saves 100 and 144 lb (65 kg) of chromium and 64 lb (29 kg) of nickel per 1000 lb (454 kg) of total plate. The clads may also be extremely thin.

Stainless-clad copper is copper sheet with stainless steel on both sides, used for making cooking utensils and food processing equipment. With stainless steel alone, heat remains localized and causes sticking and burning of foodstuffs. Copper has high heat conductivity, is corroded by some foods, and has an injurious catalytic action on milk products. Thus, the stainless-clad copper gives a conductivity of copper with the protection of stainless steel. The internal layer of copper also makes the metal easier to draw and form.

Cladding

(1) A layer of material, usually metallic, that is mechanically or metallurgically bonded to a substrate. Cladding may be bonded to the substrate by any of several processes, such as roll-cladding and explosive forming. (2) A relatively thick layer (>1 mm, or 0.04 in.) of material applied by surfacing for the purpose of improved corrosion resistance or other properties. (3) The application of a substantial coating of one type of metal to a substrate of another. For example, a strong, corrosion-prone aluminum alloy plate can be clad with a corrosion-resistant but weak "pure" aluminum. Such cladding is accomplished by rolling either a pair of the materials or a sandwich comprising a slab of the alloy between two slabs of "pure" material. Rolled gold is another example. See also *coating*, *surfacing*, and *hard facing*.

Clamping Pressure

In injection molding and transfer molding of plastics, the pressure that is applied to the mold to keep it closed in opposition to the fluid pressure of the compressed molding material, within the mold cavity (cavities) and the runner system. In blow molding, the pressure exerted on the two mold halves (by the locking mechanism of the blowing table) to keep the mold closed during formation of the container. Normally, this pressure or force is expressed in tons.

Clamshell Marks

Same as *beach marks*.

Classification

(1) The separation of ores into fractions according to size and specific gravity, generally in accordance with Stokes' law of sedimentation. (2) Separation of a metal powder into fractions according to particle size.

Clay

Clay is composed of naturally occurring sediments that are produced by chemical actions resulting during the weathering of rocks. Often clay is the general term used to identify all earths that form a paste with water and harden when heated. The primary clays are those located in their place of formation. Secondary clays are those that have been moved after formation to other locations by natural forces, such as water, wind, and ice. Most clays are composed chiefly of SiO_2 and Al_2O_3 . Clays are used for making pottery, tiles, brick, and pipes, but more particularly the better grade of clays are used for pottery and molded articles not including the fireclays and fine porcelain clays. Kaolins are the purest forms of clay. Clay is a natural mineral aggregate, consisting essentially of hydrous aluminum silicates. It is plastic when sufficiently wetted, rigid when dried en masse, and vitreous when fired to a sufficiently high temperature.

The fineness of the grain of a clay influences not only its plasticity but also such properties as drying performance, drying shrinkage, warping, and tensile, transverse, and bonding strength. For example, the greater the proportion of fine material, the slower the drying rate, the greater the shrinkage, and the greater the tendency to warping and cracking during this stage. Clays with a high fines content usually are mixed with coarser materials to avoid these problems.

For two clays with different degrees of plasticity, the more plastic one will require more water to make it workable, and water loss during drying will be more gradual because of its more extensive capillary system. The high-plasticity clay also will shrink more and will be more likely to crack.

The most important clays in the pottery industry are the ball clays and china clays (kaolin).

Commercial Clay

Commercial clays, or clays utilized as raw material in manufacturing, are among the most important nonmetallic mineral resources. The value of clays is related to their mineralogical and chemical composition, particularly the clay mineral constituents kaolinite, montmorillonite, illite, chlorite, and attapulgite. The presence of minor amounts of mineral or soluble salt impurities in clays can restrict their use. The more common mineral impurities are quartz, mica, carbonates, iron oxides and sulfides, and feldspar. In addition, many clays contain some organic material.

Mining and Processing

Almost all the commercial clays are mined by open-pit methods, with overburden-to-clay ratios ranging as high as 10^{-1} . The overburden is removed by motorized scrapers, bulldozers, shovels, or draglines. The clay is removed with draglines, shovels, or bucket loaders, and transported to the processing plants by truck, rail, aerial trainways, or belt conveyors, or as slurry in pipelines.

The clay is processed dry or, in some cases, wet. The dry process usually consists of crushing, drying, and pulverizing. The clay is crushed to egg or fist size or smaller and dried usually in rotary driers. After drying, it is pulverized to a specified mesh size such as 90% retained on a 200-mesh screen with the largest particle passing a 30-mesh screen. In other cases, the material may have to be pulverized to 99.9% finer than 325 mesh. The material is shipped in bulk or in bags. All clays are produced by this method.

Properties

Most clays become plastic when mixed with varying proportions of water. Plasticity of a material can be defined as the ability of the material to undergo permanent deformation in any direction without rupture under a stress beyond that of elastic yielding. Clays range from those that are very plastic, called fat clay, to those that are barely plastic, called lean clay. The type of clay mineral, particle size and shape, organic matter, soluble salts, adsorbed ions, and the amount and type of nonclay minerals all affect the plastic properties of a clay.

Strength

Green strength and dry strength properties are very important because most structural clay products are handled at least once and must be strong enough to maintain shape. Green strength is the strength of the clay material in the wet, plastic state. Dry strength is the strength of the clay after it has been dried.

Shrinkage

Both drying and firing shrinkages are important properties of clay used for structural clay products. Shrinkage is the loss in volume of a clay when it dries or when it is fired. Drying shrinkage is dependent on the water content, the character of the clay minerals, and the particle size of the constituents. Drying shrinkage is high in most very plastic clays and tends to produce cracking and warping. It is low in sandy clays or clays of low plasticity and tends to produce a weak, porous body.

Color

Color is important in most structural clay products, particularly the maintenance of uniform color. The color of a product is influenced by the state of oxidation of iron, the state of division of the iron minerals, the firing temperature and degree of vitrification, the proportion of Al_2O_3 , lime, and MgO in the clay material, and the composition of the fire gases during the burning operation.

Uses

All types of clay and shale are used in the structural products industry but, in general, the clays that are used are considered to be relatively low grade. Clays that are used for conduit tile, glazed tile, and sewer pipe are underclays and shales that contain large proportions of kaolinite and illite.

Clays used for brick and drain tile must be plastic enough to be shaped. In addition, color and vitrification range are very important. For common brick, drain tile, and terra-cotta, shales and surface clays are usually suitable, but for high-quality face bricks, shales and underclays are used.

Clean Surface

A service that is free of foreign material, both visible and invisible.

Cleanup Allowance

See *finish allowance*.

Clearance

(1) The gap or space between two mating parts. (2) Space provided between the relief of a cutting tool and the surface that has been cut.

Clearance Angle

The angle between a plane containing the flank of the tool and a plane passing through the cutting edge in the direction of relative motion between the cutting edge and the work. See also the terms *face mill* and *single-point tool*.

Clearance Fit

Any of various classes of fit between mating parts where there is a positive allowance (gap) between the parts, even when they are made to the respective extremes of individual tolerances that enable the tightest fit between the parts. Contrast with *interference fit*.

Clearance Ratio

In a bearing, the ratio of radial clearance to shaft radius.

Cleavage

(1) Fracture of a crystal by crack propagation across a crystallographic plane of low index or low ductility fracture. (2) The tendency to cleave or split along definite crystallographic planes. (3) Breakage of covalent bonds. (4) The effect can be visualized as layers of atoms peeling apart in contrast to ductile shear failure where the layers slide across one another. The relevant atomic planes are referred to as cleavage planes and the resultant cracks as brittle, flat, or cleavage fractures.

Cleavage Crack (Crystalline)

A crack that proceeds across the grain, that is, a transgranular crack in a single crystal or in a single grain of a polycrystalline material.

Cleavage Crack (Glass)

Damage produced by the translation of a hard, sharp object across a glass surface. This fracture system typically includes a plastically deformed groove on the damage surface, together with median and lateral cracks emanating from this groove.

Cleavage Fracture

A fracture, usually of a polycrystalline metal, in which most of the grains have failed by cleavage, resulting in bright reflecting facets. It is one type of *crystalline fracture* and is associated with low-energy *brittle fracture*. Contrast was *shear fracture*.

Cleavage Plane

A characteristic crystallographic plane or set of planes in a crystal on which *cleavage fracture* occurs easily.

Cleavage Strength

In testing of adhesive bonded assemblies, the tensile load and terms of kgf/mm (lbf/in.) of width required to cause the separation of a test specimen 25 mm (1 in.) in length.

Clenching/Clinching

The final process of tightening a mechanical joint by tightening a bolt, bending over the projecting point of a nail closing over the shank of a rivet.

Climb Cutting

Analogous to *climb milling*.

Climb Milling

Milling in which the cutter moves in the direction of feed at the point of contact.

Clink, Clinking

The noise of a crack occurring in metals, usually steel, during heating or cooling. The cracks themselves may be termed clinks. They result from restraint of thermal expansion or contraction or, during cooling from hydrogen damage.

Clinker

Generally a fused or partly fused by-product of the combustion of coal as opposed to fine ash but also including lava and portland cement clinker, and partly vitrified slag and brick.

Clip and Shave

In forging, a dual operation in which one cutting surface in the clipping die removes the *flash* and then another shapes and sizes the piece.

Close Packed Hexagonal

A crystal structure in which atoms are close packed, i.e., in contact with six others in the same layer and with three others on the layers above and below, and in which the atoms in alternate layers are aligned. Face-centered cubic, also termed cubic close packed, is similar except that every third layer is aligned.

Close(d) Annealing

Annealing in a sealed box to minimize reaction with air. In the case of steel the term may also imply subcritical annealing as opposed to full annealing. Same as *box annealing*.

Close(d) Joint

A joint in which the component faces to be welded are in contact prior to welding.

Closed Assembly Time

The time interval between completion of assembly of the parts for adhesive bonding and the application of pressure or heat, or both, to the assembly.

Closed Dies

Forging or forming impression dies designed to restrict the flow of metal to the cavity within the die set, as opposed to open dies, in which there is little or no restriction to lateral flow.

Closed Pass

A pass of metal through rolls where the bottom roll has a groove deeper than the bar being rolled and the top roll has a collar fitting into the groove, thus producing the desired shape free from *flash* or fin.

Closed Porosity

The volume fraction of all pores within a solid mass that are closed off by surrounding dense solid, and hence are inaccessible to each other and to the external surface; they thus are not detectable by gas or liquid penetration. In contrast, open pore material allows lubricant to permeate the material.

Closed-Cell Cellular Plastics

Cellular plastics in which almost all the cells are non-interconnecting.

Closed-Die Forging

The shaping of hot metal completely within the walls or cavities of two dies that come together to enclose the workpiece on all sides. The impression for the forging can be entirely either die or divided between the top and bottom dies. Impression-die forgings, often used interchangeably with the term closed-die forging, refers to a closed-die operation in which the dies contain a provision for controlling the flow of excess material, or *flash*, that is generated. By contrast, in flashless forging, the material is deformed in a cavity that allows little or no escape of excess material. See *forge*.

Close-Packed

A geometric arrangement in which a collection of equally sized spheres (atoms) may be packed together in a minimum total volume.

Close-Tolerance Forging

A forging held to unusually close dimensional tolerances so that little or no machining is required after forging. See also *precision forging*.

Closure

In fabricating of reinforced plastics, the complete coverage of a mandrel with one layer (two plies) of fiber. When the last tape circuit that completes mandrel coverage lays down adjacent to the first without gaps or overlaps, the wind pattern is said to have closed.

Cloth (Composites)

See *woven fabric* and *nonwoven fabric*.

Cloth (Powder Metallurgy)

Metallic or nonmetallic screen or fabric used for screening or classifying powders.

Cloud Point

The temperature at which a wax cloud first appears on cooling a mineral oil under specified conditions.

Cloudburst Treatment

A form of *shot peening*.

Cluster Mill

A rolling mill in which each of the two working rolls of small diameter is supported by two or more backup rolls.

CMOD

See crack opening displacement and fracture toughness.

CO₂

Carbon dioxide.

CO₂ Flux Welding Process

See CO₂ welding.

CO₂ Process

See *carbon dioxide process*.

CO₂ Process

A process for producing strong sand molds for casting. The sand is mixed first with a quantity of 3%–5% sodium silicate solution just sufficient to lightly coat the grains but allow normal molding. After the mold is formed CO₂ is blown through to react with the silicate and strongly bind the sand. Also termed the *sodium silicate* or the *silicate process*.

CO₂ Welding

See preferred term *gas metal arc welding*.

CO₂ Welding

A form of metal inert gas (MIG) welding or gas metal arc welding (GMAW) in which the electric arc is struck between the component to be welded and a continuously fed bare wire filler electrode. Carbon dioxide is delivered, usually via the wire feed system, to provide a protective gas shroud for the weld zone. The process is commonly used for steel with which CO₂ is effectively inert. CO₂ Flux Welding is similar except that the consumable electrode is a flux coated wire or a flux filled tube.

Coagulation

Precipitation of a polymer dispersed in a latex.

C

Coal

A general name for a black mineral formed of ancient vegetable matter, and employed as a fuel and for destructive distillation to obtain gas, coke, oils, and coal-tar chemicals. Coal is composed largely of carbon with smaller amounts of hydrogen, nitrogen, oxygen, and sulfur. It was formed in various geological ages and under varying conditions, and it occurs in several distinct forms. *Peat* is the first stage, followed by lignite, bituminous coal, and anthracite, with various intermediate grades. The mineral is widely distributed in many parts of the world. The value of coal for combustion purposes is judged by its fixed carbon content, volatile matter, and lack of ash. It is also graded by the size and percentage of lumps. The percentage of volatile matter declines from peat to anthracite, and the fixed carbon increases. A good grade of coal for industrial powerplant use should contain 55%–60% fixed carbon and not exceed 8% ash. Finely ground coal, or *powdered coal*, is used for burning in an air blast-like oil, or it may be mixed with oil. Coal in its natural state absorbs large amounts of water and also, because of the impurities in irregular sizes, is not so efficient a fuel as the *reconstructed coal* made by crushing and briquetting lignite or coal and waterproofing with a coating of pitch. *Anthracite powder* is used as a filler in plastics.

Low-sulfur coal burns cleaner than regular coal, but its heating value is much less so that it is uneconomical as a fuel. Increasing amounts of coal are being used for production of gas and chemicals. By the hydrogenation of coal much greater quantities of phenols, cresols, aniline, and nitrogen-bearing amines can be obtained than by means of by-product coking, and low grades of coal can be used. The finely crushed coal is slurred to a paste with oil, mixed with a catalyst, and reacted at high temperature and pressure. *Synthesis gas*, used for producing gasoline and chemicals, is essentially a mixture of carbon monoxide and hydrogen. It is made from low-grade coals.

Coalesced Copper

Massive oxygen-free copper made by briquetting ground, brittle cathode copper, then sintering the briquettes in a pressurized reducing atmosphere, followed by hot working.

Coalescence

(1) The union of particles of a dispersed phase into larger units, usually affected at temperatures below the fusion point. (2) Growth of grains at the expense of the remainder by absorption or the growth of a phase or particle at the expense of the remainder by absorption or reprecipitation. (3) Examples include the coalescence of voids during creep or the coalescence of carbides in steel where a large number of fine particles can, by a process of diffusion, coalesce to a small number of coarse particles. (4) The bonding that results when powders are sintered. (5) In the context of welded or brazed joints, the term indicates a satisfactory bond between components.

Coarse Fraction

The large particles in a metal powder spectrum.

Coarse Grains

Grains larger than normal for the particular wrought metal or alloy or of a size that produces a surface roughening known as *orange peel* or alligator skin.

Coarsening

An increase in grain size, usually, but not necessarily, by *grain growth*.

Coarsening

The increase in grain size by the process of grain growth or, in steel, the increase in size, with associated reduction in number, of carbide particles or pearlite plates. See *steel*.

Coated Abrasive

An abrasive product (sandpaper, for example) in which a layer of abrasive particles is firmly attached to a paper, cloth, or fiber backing by means of glue or synthetic-resin adhesive.

Coated Electrode

See preferred term *covered electrode* and *lightly coated electrode*.

Coated Fabrics

The first coated fabric was a rubberized fabric produced in Scotland by Charles Macintosh in 1823 and known as *Macintosh cloth* for rainwear use. The cloth was made by coating two layers of fabric with rubber dissolved in naphtha and pressing them together, making a double fabric impervious to water. *Rubberized fabrics* are made by coating fabrics, usually cotton, with compounded rubber and passing between rollers under pressure. The vulcanized coating may be no more than 0.003 in. (0.008 cm) thick, and the resultant fabric is flexible and waterproof. But most coated fabrics are now made with synthetic rubbers or plastics, and the base fabric may be of synthetic fibers, or a thin plastic film may be laminated to the fabric.

Coated fabrics now have many uses in industrial applications, and the number of variations with different resins and backing materials is infinite. They are usually sold under trade names and are used for upholstery, linings, rainwear, bag covers, book covers, tarpaulins, outerwear, wall coverings, window shades, gaskets, and diaphragms. Vinyl-type resins are most commonly used, but for special purposes other resins are selected to give resistance to wear, oils, or chemicals.

Vinyl-coated fabrics are usually tough and elastic and are low cost, but unless specially compounded are not durable. Many plastics in the form of latex or emulsion are marketed especially for coating textiles. Water dispersions of acrylic resins are specifically made for this purpose. Coatings cure at room temperature, and have high heat and light stability, give softness flexibility to the fabric, and withstand repeated dry-cleaning. A water emulsion of a copolymer of vinyl pyrrolidone with ethyl acrylate forms an adherent, tough, and chemical-resistant coating. *Geon latex* is a water dispersion of polyvinyl chloride resin. Polyvinyl chloride of high molecular weight is resistant to staining, abrasion, and tearing and is used for upholstery fabrics. The base cloth may be of various weights from light sheetings to heavy ducks. They may be embossed with designs to imitate leather.

One of the first upholstery fabrics to replace leather was *Fabrikoid*, of DuPont. It was coated with a cellulose plastic and came in various weights, colors, and designs, especially for automobile seating and book covers. *Armalon* is twill or sateen fabric coated with ethylene plastic for upholstery. For some uses, such as

for draperies or industrial fabrics, the fabric is not actually coated, but is impregnated, either in the fiber or in the finished cloth, to make it water-repellent, immune to insect attack, and easily cleaned.

Impregnated fabrics may have only a thin, almost undetectable surface coating on the fibers to make them water-repellent and immune to bacterial attack, or they may be treated with fungicides or with flame-resistant chemicals or waterproofing resins. *Stabilized fabrics*, however are not waterproofed or coated, but are fabrics of cotton, linen, or wool that have been treated with a water solution of urea formaldehyde or other thermosetting resin to give them greater resiliency with resistance to creasing and resistance to shrinking and washing. *Shrinkproof fabrics* are likewise not coated fabrics, but have a light impregnation of resins that usually remains only in the core of the fibers. The fabric retains its softness, texture, and appearance, but the fibers have increased stability. Various resin materials are marketed under trade names for creaseproofing and shrinkproofing fabrics.

Under the general name of protective fabrics, coated fabrics are now marketed by use characteristics rather than by coating designation since resin formulations vary greatly in quality. For example, the low-cost grades of vinyl resins may be hard and brittle at low temperatures and soft and rubbery in hot weather, and thus unsuitable for all-weather tarpaulins. Special weaves of fabrics are used to give a high tear strength with light weight, and the plastic may be impregnated, coated on one side or both, bonded with an adhesive or electronically bonded, or some combination of all these. Flame resistance and static-free qualities may also be needed. Many companies have complete lines to meet definite needs.

Coating

(1) A relatively thin layer (<1 mm, or 0.04 in.) of material applied by surfacing for the purpose of corrosion prevention, resistance to high-temperature scaling, wear resistance, lubrication, or other purposes. (2) Any process of applying a surface layer to a component, or the layer itself. The term is sometimes used in contrast to cladding to imply a relatively thin surface layer, less than about 1 mm. (3) The layer of flux and other materials on some welding electrodes.

Coating Density

The ratio of the determined density of a coating to the theoretical density of the material used in the coating process. Usually expressed as percent of theoretical density.

Coating Strength

A measure of the cohesive bond within a coating, as opposed to coating-to-coating substrate bond; the tensile strength of a coating.

Coating Stress

The stresses in a coating resulting from rapid cooling of molten or semi-molten particles as they impact the substrate.

Coatings

Plastic, metal, or ceramic coatings can be applied to the surface of a material in a variety of ways to achieve desired properties.

Coatings improve adherence, corrosion resistance, abrasion resistance, and electrical or optical properties. They can be applied by wet or dry techniques, with simple or complex equipment.

The choices are almost limitless because almost any coating material offers some degree of protection as long as it retains its integrity. If it provides a continuous barrier between the substrate and the environment, even a thin, decorative coating can do the job in a relatively dry and mild environment.

Metal Coatings

Many new materials have been developed, but steel remains the principal construction material for automobiles, appliances, and industrial machinery. Because of the vulnerability of steel to attack by aggressive chemical environments or even from simple atmospheric oxidation, coatings are necessary to provide various degrees of protection. They range from hot-dipped and electroplated metals to tough polymers and flame-sprayed ceramics.

In general, corrosive environments contain more than one active material, and the coating must resist penetration by a combination of oxidizers, solvents, or both. Thus, the best barrier is one that resists “broadband” corrosion.

Physical integrity of the coating is as important as its chemical barrier properties in many applications. For instance, coatings on impellers that mix abrasive slurries can be abraded quickly; coatings on pipe joints will cold-flow away from a loaded area if the creep rate is not low; and coatings on flanges and support brackets can be chipped or penetrated during assembly if impact strength is inadequate. Selecting the best coating for an application requires evaluating all effects of the specific environment, including thermal and mechanical conditions.

Zinc

One of the most common and inexpensive protection methods for steel is provided by zinc. Zinc-coated, or galvanized, steel is produced by various hot-dipping techniques, but more steel companies have moved into electrogalvanizing so they can provide both.

Oxidation protection of steel by zinc operates in two ways—first as a barrier coating, then as a sacrificial coating. If the zinc coating is scratched or penetrated, it continues to provide protection by galvanic action until the zinc layer is depleted. This sacrificial action also prevents corrosion around punched holes and at cut edges.

The grades of zinc-coated steel commercialized in recent years have been designed to overcome the drawbacks of traditional galvanized steel, which has been difficult to weld and to paint to a smooth finish. The newer materials are intended specifically for stamped automotive components, which are usually joined by spot welding and which require a smooth, Class A painted finish.

Aluminum

Two types of aluminum-coated steel are produced, each a different kind of corrosion protection. Type I has a hot-dipped Al-Si coating to provide resistance to both heat and corrosion. Type 2 has a hot-dipped coating of commercially pure aluminum, which provides excellent durability and protection from atmospheric corrosion. Both grades are usually used unpainted.

Type I aluminum-coated steel resist heat scaling to 677°C and has excellent heat reflectivity to 482°C. Nominal aluminum-alloy coating is about 1 mil on each side. The sheet is supplied with a soft, satiny finish. Typical applications include reflectors and housings for industrial heater panels, interior panels and heat exchangers for residential furnaces, microwave ovens, automobile and truck muffler systems, heat shields for catalytic converters, and pollution-control equipment.

Type 2 aluminized steel, with an aluminum coating of about 1.5 mil on each side, resists atmospheric corrosion and is claimed to outlast zinc-coated sheet in industrial environments by as much as 5–1. Typical applications are industrial and commercial roofing and siding, drying ovens, silo roofs, and housings for outdoor lighting fixtures and air-conditioners.

Electroplating

Use of protective electroplated metals has changed in recent years, mainly because of rulings by the Environmental Protection Agency (EPA). Cyanide plating solutions and cadmium and lead-bearing finishes are severely restricted or banned entirely. Chromium and nickel platings are much in use, however, applied both by conventional electroplating techniques and by new, more efficient methods such as fast rate electrodeposition (FRED), which has also been used successfully to deposit stainless steel on ferrous substrates.

Functional chromium, or “hard chrome,” plating is used for anti-galling and low-friction characteristics as well as for corrosion protection. These platings are usually applied without copper or nickel underplates in thicknesses from about 0.3 to 2 mil. Hard-chrome plating is recommended for use in saline environments to protect ferrous components.

Nickel platings, in thickness from 0.12 to 3 mil, are used in food-handling equipment, on wear surfaces in packaging machinery, and for cladding in reaction vessels.

Electroless nickel plating, in contrast to conventional electroplating, operates chemically instead of using an electric current to deposit metal. The electroless process deposits a uniform coating regardless of substrate shape, overcoming a major drawback of electroplating—the difficulty of uniformly plating irregularly shaped components. Conforming anodes and complex fixturing are unnecessary in the electroless process. Deposit thickness is controlled simply by controlling immersion time. The deposition process is autocatalytic, producing thicknesses from 0.1 to 5 mil.

Proprietary electroless-plating systems contain, in addition to nickel, elements such as phosphorous, boron, and/or thallium. A relatively new composition, called the polyalloy, features three or four elements in the bath. These products are claimed to provide superior wear resistance, hardness, and other properties, compared with those of generic electroless-plating methods.

One polyalloy contains nickel, thallium, and boron. Originally developed for aircraft gas turbine engines, it offers excellent wear resistance. Comparative tests show that relative wear for a polyalloy-coated part is significantly less than that for hard chromium and Ni–P coatings.

In general, Ni–B coatings are nodular. As coating thickness increases, nodule size also increases. Because the columnar structure of the coating flexes as the substrate moves, Ni–B resists chipping and wear.

Adhesion quality depends on factors such as substrate material, part preparation, and contamination. Although it is excellent for tool steels, stainless steel, high-performance nickel- and cobalt-base alloys, and titanium, a few metal substrates are not compatible. These include metals with high zinc or molybdenum content, aluminum, magnesium, and tungsten carbide. Modifications can, however, eliminate this incompatibility.

Another trend in composite electroless plating appears to be toward codeposition of particulate matter within a metal matrix. These coatings are commercially available with just a few types of particulates—diamond, SiC, Al₂O₃, and polytetrafluoroethylene (PTFE)—with diamond heading the list in popularity.

These coatings can be applied to most metals, including iron, carbon steel, cast iron, aluminum alloys, copper, brass, bronze, stainless steel, and high-alloy steels.

Conversion Coatings

Electroless platings are more accurately described as conversion coatings, because they produce a protective layer or film on the metal surface by means of a chemical reaction. Another conversion process, the black oxide finish, has been making progress in applications ranging from fasteners to aerospace. Black oxide is gaining in popularity because it provides corrosion resistance and aesthetic appeal without changing part dimensions.

On a chemical level, black oxidizing occurs when the Fe within the surface of the steel reacts to form magnetite (Fe₃O₄). Processors use inorganic blackening solutions to produce the reaction. Oxidizing salts are first dissolved in water, then boiled and held at 138°C–140°C. The product surface is cleaned in an alkaline soak and then rinsed before immersion in the blackening solution. After a second rinse, the finish is sealed with rust preventatives, which can produce finishes that vary from slightly oily to hard and dry.

Black oxidizing produces a microporous surface that readily bonds with a topcoat. For example, a supplemental oil topcoat can be added to boost salt-spray resistance to the same level as that of zinc plate with a clear chrome coating (100–200 h).

Black oxide can be used with mild steel, stainless steel, brass, bronze, and copper. As long as parts are scale free and do not require pickling, the finish will not produce hydrogen embrittlement or change part dimensions. Operating temperatures range from cryogenic to 538°C.

Chromate conversion coatings are formed by the chemical reaction that takes place when certain metals are brought in contact with acidified aqueous solutions containing basically water-soluble chromium compounds in addition to other active radicals. Although the majority of the coatings are formed by simple immersion, a similar type of coating can be formed by an electrolytic method.

Protective chromate conversion coatings are available for zinc and zinc alloys, cadmium, aluminum and aluminum alloys, copper and copper alloys, silver, magnesium and magnesium alloys. The appearance and protective value of the coatings depends on the base metal and on the treatment used.

Chromate conversion coatings both protect metals against corrosion and provide decorative appeal. They also have the characteristics of low electrical resistance, excellent bonding characteristics with organic finishes, and can be applied easily and economically. For these reasons the coatings have developed rapidly, and they are now one of the most commonly used finishing systems. They are particularly applicable where metal is subjected to storage environments such as high humidity, salt, and marine conditions.

The greatest majority of chromate conversion coatings are supplied as proprietary materials and processes. These are available usually as liquid concentrates or powdered compounds that are mixed with water. In the case of the powdered compounds, they are often adjusted with additions of acid for normal operation.

Chromate conversion coatings are formed immersing the metal in an aqueous acidified chromate solution consisting substantially of chromic acid or water-soluble salts of H₂CrO₃ together with various catalysts or activators. The chromate solutions, which contain either organic or inorganic active radicals or both, must be acid and must be operated within a prescribed pH range.

Maximum corrosion protection is obtained by using drab or dark bronze coatings on zinc and cadmium surfaces, and yellow to brown-colored coatings on the other metals. Lighter iridescent

yellow type coatings generally provide medium protection, and the clear-bright type coatings, produced either in one dip or by leaching, provide the least protection.

Chromate conversion coatings provide maximum corrosion protection in salt spray or marine types of environment, and in high humidity such as encountered in storage, particularly where stale air with entrapped water may be present. They also provide excellent protection against tarnishing, staining, and finger marking, or other conditions that normally produce surface oxidation.

Olive drab type coatings are widely used on military equipment because of their high degree of corrosion protection coupled with a nonreflective surface. Iridescent yellow coatings are widely used for corrosion protection where appearance is not a deciding factor. The clear-bright chemically polishing type coatings for zinc and cadmium have been widely used to simulate nickel and chromium electroplate and are primarily used for decorative appeal rather than corrosion protection. Where additional corrosion protection or abrasion resistance is desired, these clear coatings act as an excellent base for a subsequent clear organic finish.

Heavy olive drab and yellow coatings for zinc, cadmium, and aluminum can be dyed various colors. Generally speaking, the dyed colors are used for identification purposes only since they are not lightfast and will fade upon exposure to direct sunlight or other sources of ultraviolet.

Because of their low electrical resistance, chromate conversion coatings are widely used for electronics equipment. Surface resistance depends on the type and thickness of the film deposited, the pressure exerted at the contact, and the nature of the contact. Low-resistance coatings are particularly important on aluminum, silver, magnesium, and copper surfaces.

Chromate conversion coatings can also be soldered and welded. A chromate coating on aluminum, for example, facilitates heliac welding. Because of the slight increase in electrical resistance, an adjustment in current (depending upon the thickness of the coating) must be made to satisfactorily spot-weld. Soldering, using rosin fluxes, can be performed on cadmium-plated surfaces that have been treated with clear bright chromate conversion coatings. Clear, bright coatings on zinc-plate surfaces and colored coatings on both zinc and cadmium necessitate the use of an acid flux or removal of the film by an increase in soldering iron temperature, which burns through the coating, or by mechanical abrasion, which removes the film and provides a clean metal surface for the soldered joint.

Most chromate conversion treatments are applied by simple immersion in an acidified chromate solution. Because no electrical contacts need be made during immersion, the coatings can be applied by rack, bulk, or strip line operation. Under special situations, swabbing or brush coating can be used where small areas must be coated, as in a touch-up operation.

Chromate conversion coatings can also be applied by an electrolytic method in which the electrolyte is composed essentially of water-soluble chromium compounds and other radicals operated at neutral or slightly alkaline pH. This type of application is limited primarily to rack-type operation.

In general, processing can be placed in two categories: (1) over freshly electroplated surfaces; and (2) over electroplated surfaces that have been aged or oxidized, or other metal surfaces such as zinc diecastings, wrought metals, or hot-dipped surfaces.

Sputtering

Formally used primarily to produce integrated-circuit components, sputtering has moved on to large, production-line jobs such as "plating" of automotive trim parts. The process deposits thin,

adherent films, usually of metal, in a plasma environment on virtually any substrate.

Sputtering offers several advantages to automotive manufacturers for an economical replacement for conventional chrome plating. Sputtering lines are less expensive to set up and operate than plating systems. And because sputtered coatings are uniform as well as thin, less coating material is required to produce an acceptable finish. Also, pollution controls are unnecessary because the process does not produce any effluents. Finally, sputtering requires less energy than conventional plating systems.

Chrome coating of plastics and metals is only one application for sputtering. The technique is not limited to depositing metal films. PTFE has successfully been sputtered on metal, glass, paper, and wood surfaces. In another application, cattle bone was sputtered on metallic prosthetic devices for use as hip-bone replacements. The sputtered bone film promotes bone growth and attachment to living bone.

Sputtering is the only deposition method that does not depend on melting points and vapor pressures of refractory compounds such as carbides, nitrides, silicides, and borides. As a result, films of these materials can be sputtered directly onto surfaces without altering substrate properties.

Much sputtering has been aimed at producing solid-film lubricants and hard, wear-resistant refractory compounds. NASA is interested in these tribological applications because coatings can be sputter-deposited without a binder, with strong adherence, and with controlled thickness on curved and complex-shaped surfaces such as gears and bearing retainers, races, and balls. Also, because sputtering is not limited by thermodynamic criteria (unlike most conventional processes that involve heat input), film properties can be tailored in ways not available with other deposition methods.

Most research on sputtered solid-lubricant films has been done with MoS₂. Other films that have been sputtered are WC, TiN, PbO₂, gold, silver, tin, lead, indium, cadmium, PTFE, and polyimide (PI). Of these coatings, the gold-colored TiN coatings are most prominent.

TiN coatings are changing both the appearance and performance of high-speed steel metal-cutting tools. Life of TiN-coated tools, according to producers' claims, increases by as much as tenfold, metal-removal rates can be doubled, and more regrinds are possible before a tool is discarded or rebuilt.

Sputter Coating Process

The SCXTM sputter coating process, a proprietary, computer-aided process developed by Engelhard-CLAL, Carteret, NJ, a producer of high-purity materials, enables the coating of base or refractory metals with precious metals. The source of the coating material can be almost any metallic composition. A major benefit of sputtering is the ability to deposit alloys or compounds that cannot be mechanically worked or alloyed as is required in the cladding process. By fabricating a segmented target comprising of two or more individual elements, a deposition can be made that is a uniformly dispersed "alloy" of the constituents.

SCX sputtering is conducted at low temperatures (<300°C), permitting deposition on plastics and other temperature-sensitive materials in addition to metals. Conducted at reduced pressures of inert gases, entrapped gases are kept to a minimum. Finally, by replacing the inert gas with a reactive gas such as H₂, N₂, or O₂, a compound formed by the gas can be deposited. This permits the reaction of very interesting coatings, such as nitrides, hydrides, and oxides. The unique sputter coating process makes it possible to attain very thin as well as relatively thick coatings equally as well in the range of 1/2 to over 6 µm.

Typical substrate dimensions are wire: 0.08–1 mm diameter, continuous lengths up to 3000 m at 0.08 mm diameter, and 300 m at 0.89 mm diameter; ribbon: 0.017–0.50 mm thick and widths from 0.25 to 3.2 mm, continuous lengths from 120 to 500 m; rods: 3.2 mm diameter by 508 mm long; metallic foil: 0.05 mm thick and up, to 102 × 508 mm window dimension; polymeric: 0.25 mm thick and up, to 102 × 508 mm window; rigid metallic and non-metallic: up to 127 mm thick and up to 102 × 508 mm window dimension. Flexible and discrete parts can be coated selectively on one or both sides.

Application to Power Tube Grids

Power tube grids control the flow of tube current by providing a bias between the cathode and anode. Semiconductor devices have replaced the bulk of electron tube usage, especially in receiving applications. However, in extremely high-power applications, the Triode style thermal emissions tube still finds global use. The electron tube is expected to provide long-lasting, high-quality performance throughout the typical frequency range of 20 kHz to over 20 GHz, with grid temperatures from 600°C to 1300°C, depending on the application. Secondary electron emission is of major concern to tube designers. Without controls or limits, a tube could easily become unstable and quickly self-destruct.

Platinum-coated molybdenum and tungsten are traditional materials for grid construction. Traditional platinum-clad molybdenum grid wire is produced with very thick precious metal coatings because it is difficult to produce claddings without base material breakthrough, and the molybdenum tends to diffuse through the platinum, embrittling the grid as well as causing an increase in emission. The SCX-PC sputter coating process accomplishes the same function as cladding, but with a precious metal savings of 15%–30%. This is achieved by introducing a diffusion barrier into the coating during the manufacturing process, which effectively prohibits the interdiffusion of the core and the coating.

Other unique coatings include SCXPZC, which includes zirconium in the deposition process to permit higher-temperature grid usage with closer cathode spacing, and SCX-TH, which produces titanium-hydride (TiH₂) coatings to control primary and secondary emissions and enables the grid to act as a getter for nascent gas molecules.

Ion Plating

The basic difference between sputtering and ion plating is that sputtered material is generated by impact evaporation and transferred by a momentum transfer process. In ion plating, the evaporant is generated by thermal evaporation. Ion plating combines the high throwing power of electroplating, the high deposition rates of thermal evaporation, and the high energy impingement of ions and energetic atoms of sputtering and ion-implantation processes.

The excellent film adherence of ion-plated films is attributed to the formation of a graded interface between the film and substrate, even where the two materials are incompatible. The graded interface also strengthens the surface and subsurface zones and increases fatigue life.

The high throwing power and excellent adherence makes possible the plating of complex three-dimensional configurations such as internal and external tubing, gear teeth, ball bearings, and fasteners. Gears for space applications, for example, have been ion plated with 0.12–0.2 μm of gold for lubrication and to prevent cold welding of the gear pitch line. Ion plating has also been used, on a production basis to plate aluminum on aircraft landing-gear components for corrosion protection.

Ion plating is also one of the two methods used to deposit diamond-like coatings (DLCs). A relative newcomer to the coatings field, DLCs are commonly made from hydrocarbon (often methane) and H₂ gases heated to 2000°C. The carbon coatings are prized for their wear resistance, as well as electrical and optical properties. Although they represent a huge potential, present DLCs are at the earliest stages of commercialization. However, their wide range of properties, along with their relatively low-cost, leads many to predict huge growth in DLCs.

Researchers have proposed that the coatings be used to improve wear resistance in tool bits, as electronic heat sinks, and to boost wear and corrosion resistance in optical materials.

Chemical vapor deposition (CVD) is the method most often used to deposit DLCs. Adjusting deposition conditions allows the processor to change the coating from graphite to diamond-like. One process used at Battelle deposits the DLC in a gas atmosphere at reduced pressure without a fixed target. This plasma-assisted CVD allows large workpieces to be coated on all sides without turning. However, substrates must be heated to roughly 800°C when using CVD.

Reduced substrate temperatures are offered by dual ion-beam-enhanced deposition. Substrate temperature reaches only 66°C, and the dual ion-beam process does not rely on epitaxial growth for its formation as CVD does. Epitaxial growth requires a crystalline substrate; because dual ion-beam processing is free of this need, it enables amorphous materials to be coated as well.

Materials that are compatible with the Diod process include ferrous and nonferrous metals, glasses, ceramics, plastics, and composites. In addition to the Diod coating, dual ion-beam enhanced deposition can apply metallic coatings to fiber-reinforced carbon-carbon materials.

The basic ion-implantation process sends beams of elemental atoms (produced in a particle accelerator) into the surface of the target component. With dual ion-beam enhanced deposition, two simultaneous beams are used. One beam continuously sputters carbon onto the surface, providing the carbon material necessary to grow a diamond film. A second beam, consisting of inert gas at higher energy, drives some of the diamond layer into the interface zone. Then, the energy of the second beam is reduced to allow diamond growth. Implanting diamond material within the interface zone optimizes adhesion.

Technologies developed for electronic and optical thin films are often transferred into the engineering coatings sector, leading to a wider use of ion- and plasma-based techniques.

A novel nonequilibrium plasma treatment method with unusual characteristics is now being developed by EA Technology Ltd. of Capenhurst, near Chester, Great Britain. The process acts like a low-pressure, nonthermal glow discharge. Although it appears to provide many of the conditions needed for plasma surface engineering, the process runs at atmospheric pressure. Atmospheric deposition is generally much simpler than traditional vacuum plasma deposition, and its higher reactant concentrations make it much faster and, therefore, more cost-effective.

The equipment needed for this new approach is little more than a modified commercial microwave oven in which the plasma is sustained within a flask by microwave energy. Processing can be done either within the plasma or in a downstream gas that flows through the flask. In-plasma treatment is more energetic. Those materials that can withstand high temperatures can be coated within the flask. Downstream processing is easier and particularly effective at coating epoxies and polymers such as polymethyl methacrylate with materials such as TiO₂. This technique improves the weather resistance of the surface. The plasma can even be used to break down noxious gases such as volatile organics with more than 97% efficiency.

Vacuum Plasma Processing

This is the heart of advanced physical vapor deposition (PVD) coatings used on tools such as molds, dies, drills, and cutters. Although TiN is the most widely used of these coatings, many demanding applications now use TiAlN. High-quality PVD coatings are produced when electron beams evaporate the coating material while N₂-rich plasma bombards the substrates. Electron beams cannot be used to evaporate alloys such as TiAl, since the vapor pressure of aluminum is 100 times higher than that of titanium. However, to overcome this problem, a new control technology has been developed for electron-beam deposition systems. This technology measures optical emissions from elements in the plasma, picking up characteristic titanium and aluminum emission lines. These are used to control individual electron-beam sources for alloy elements.

As a result, users can control the composition of the alloy coating—they can even modify the gradation of the coating chemistry, a technique not possible with alloy arc and sputter sources.

C-coated components, when compared to nitrided, nickel, and chromium coatings, exhibit improved wear-resisting performance. In particular, Balinit® C WC/C coatings are claimed to offer the proper combination of low coefficient of friction and high hardness needed by highly loaded automotive and machine parts.

Balinit C WC/C coatings are made of hard WC particles in a soft amorphous carbon matrix. Ion bombardment of a WC target removes coating material for deposition onto component surfaces under controlled conditions. Several applications demonstrate the ability of the material to solve wear problems:

- A coating of WC/C, specifically developed for highly stressed machine components operating under less-than-optimum lubricating conditions, has given design engineers a way out of such predicaments. Produced by PVD, WC/C is said to improve seizure resistance and reduce failure due to particle-contaminated hydraulic oils.
- Pump pistons coated with Balinit C operate longer than nitrided pistons or nickel- and chromium-coated pistons. Replacement of sliding shoes made from bronze with Balinit C coated steel also cuts down on wear.
- Application results in a low coefficient of friction and “smoothing” of the surface of the part. Hardness measures 1000 VHN (25 g); thickness is approximately 3 μm.
- Balinit C WC/C coatings, with a maximum working temperature of 300°C, are at present used in racing, as well as industrial gear systems.

In tribological tests conducted on CrN, TiAlN, TiAlCN, TiCN, TiCN + C, TiN + C, TiB₂, WC, and molybdenum coatings for load capacitance, adhesion power, abrasion force, hardness, and fatigue strength showed TiAlN, the very hard, metallic coating used on cutting tool inserts, gave the best results. Unlike cutting tools, however, bearing components cannot be coated in a standard CVD process at temperatures over 500°C. Even with a specialty developed PVD process, which deposits hard coatings with high adhesion power at a temperature level of only 160°C, bearing rings must undergo special annealing after final grinding at a temperature of approximately 240°C to achieve the roundness deviation after coating within the normal manufacturing tolerance range.

Thermal Spraying

Arc spraying, a form of thermal spraying of metals, is done on a prepared (usually *grit-blasted*) metal surface, using a wire-arc gun.

The coating metal is in the form of two wires that are fed at rates that maintain a constant distance between their tips. An electric arc liquefies the metal, and an air spray propels it onto the substrate. Because particle velocity can be varied considerably, the process can produce a range of coating finishes from a fine to a coarse texture.

Arc-sprayed coatings are somewhat porous, as they are composed of many overlapping platelets. Used in applications where appearance is important, thermally sprayed coatings can be sealed with pigmented vinyl copolymers or paints, which usually increase the life of the metal coating. Arc-sprayed coatings are thicker than those applied by hot dipping, ranging from 3 to 5 mil for light-duty, low-temperature applications to 7 to 12 mil for severe service.

Because zinc and aluminum are, under most conditions, more corrosion resistant than steel, they are the most widely used spray-coating metals. In addition, since both metals are anodic to steel, they act galvanically to protect ferrous substrates.

In general, aluminum is more durable in acidic environments, and zinc performs better in alkaline conditions. For protecting steel in gas or chemical plants, where temperatures might reach 204°C, aluminum is recommended. Zinc is preferred for protecting steel in fresh, cold waters; in aqueous solutions above 66°C, aluminum is the usual choice.

For service to 538°C, a thermally sprayed aluminum coating should be sealed with a silicone-aluminum paint. Between 538°C and 899°C, the aluminum coating fuses and reacts with the steel base metal, forming a coating that, without being sealed, protects the structure from an oxidizing environment. And, for continuous service to 982°C, a nickel-chrome alloy is used, sometimes followed by aluminum.

In Europe, where thermally sprayed metal coatings for corrosion protection have been far more widely used than in the United States, many structures such as bridges are still in good condition after as long as 40 years, with minimum maintenance. Other applications include exhaust-gas stacks, boat hulls, masts, and many outdoor structures.

Thermal spraying has become much more than a process for rebuilding worn metal surfaces. Thanks to sophisticated equipment and precision control, it is now factored into the design process, producing uniform coatings of metals and ceramics. With some of the processes, even gradated coatings can be applied. This is done by coating the substrate with a material that provides a good bond and that has compatible expansion characteristics, then switching gradually to a second material to produce the required surface quality such as wear resistance, solderability, or thermal-barrier characteristics.

Plasma Spraying

Plasma-spray coating relies on a hot, high-speed plasma flame (N₂, H₂, or argon) to melt a powdered material and spray it onto the substrate. A DC arc is maintained to excite gases into the plasma state.

The high-heat plasma (in excess of 7075°C) enables this process to handle a variety of coating materials—most metals, ceramics, carbides, and plastics. Although most coating materials are heated to well beyond their melting points, substrate temperatures commonly remain below 121°C.

This process has found wide acceptance in the aircraft industry. Plasma-sprayed metallic coatings protect turbine blades from corrosion, and sprayed ceramics provide thermal-barrier protection for other engine parts.

Proprietary refinements in plasma-spray technology include a wear-resistance coating material that lends itself to forming amorphous/microcrystalline phases when plasma sprayed. The resultant coating provides excellent corrosion resistance with minimal

oxidation at higher temperatures. This promises to eliminate problems of work-hardened crystalline coatings that chip or delaminate in response to stress, which have previously been taken care of by expensive alloying elements.

Another amorphous alloy development involves a crystalline material that, upon abrasive wear, transforms to an amorphous hard-phase alloy. The top layer, 3–5 μm thick, results in hardness levels over 1300 Vickers. Wear tests have indicated this material is superior to more expensive WC coatings.

Detonation gun coatings considered by many to be an industry standard, use a detonation wave to heat and accelerate powdered material to 732 mm/s. In the line-of-sight process, each individual detonation deposits a circle of coating with a 2.54 cm diameter and 2 μm thickness. Coatings, thus, consist of multiple layers of densely packed lenticular particles tightly bonded to the surface.

The Super D-Gun has been developed to increase particle velocities. New coatings (the UCAR 2000 Series) applied with the gun offer improved wear resistance without affecting fatigue performance. The system has been targeted for fatigue-sensitive aircraft components.

Other low-pressure plasma-spray (LPPS) coatings protect turbine vanes by improving the sulfidation and oxidation resistance of complex components. Inert-atmosphere LPPS systems are an effective means for applying complex corrosion-resistant coatings such as NiCoCrAlY to high-temperature engine components.

PS300 is a self-lubricating solid coating material for use in sliding contacts at temperatures up to 800°C. PS300 is a composite of metal-bonded CrO_2 with $\text{BaFl}_2/\text{CaFl}_2$ eutectic and silver as solid lubricant additives. The “PS” in the name of this and other self-lubricating, high-temperature composite materials signifies that the material is applied to a substrate by plasma spraying of a powder blend of its constituents.

Spray Coatings

Stabilized Zirconia (ZrO_2)

Yttria-stabilized zirconia (YZP) represents the bulk of all sprayed ceramics. This material is used primarily for thermal barrier coatings (TBCs) in aircraft, rocket, and reciprocating engines. TBCs are applied to engine components to lower substrate temperatures so that combustion gas temperatures can be higher, thereby increasing engine power and efficiency and lowering emissions. Stabilized ZrO_2 is unique for its high CTE and low thermal conductivity. The high CTE correlates well with the base metals to which ZrO_2 is commonly applied, reducing stresses that are induced by differential expansion. Plasma-sprayed YZP is also reasonably resistant to thermal fatigue and chemical attack.

Other elements used to stabilize ZrO_2 include the oxides of magnesium, calcium, and cerium. Phase stabilization is used to mitigate the large volume change that ZrO_2 undergoes during heating to and cooling from service temperatures. The phase transformation from low-temperature monoclinic to high-temperature tetragonal can be arrested by the inclusion of stabilizing components such as YO_2 . Fully stabilized ZrO_2 maintains a cubic structure throughout heating. Partially stabilized ZrO_2 , which has both cubic and tetragonal phases, is reported to be tougher and to have a better match of CTE with engine materials.

MCRALYS

Metallic coatings are used between the ceramic coating and substrate both to enhance bonding and to provide a barrier that prevents substrate oxidation and corrosion. As a class, these materials are

denoted by the term MCRALY, which is derived from the components: a base metal (M), chromium (CR), aluminum (AL), and yttria (Y). The M component is iron (Fe), cobalt (Co), or nickel (Ni), singly or in combination. The coatings are then called FECRALY, COCRALY, NICRALY, and so forth.

Recent advances in thermal spraying have focused on controls. Process control includes barfeedstock, materials, and processing parameters. Historically, thermal spray coatings have been applied at a confidence level of around 70.

Applications

Common use of thermally sprayed YZP involves net-shape manufacturing. O_2 sensors for automobile emission control systems are manufactured by applying the coatings of YZP to remove mandrels. When the mandrel is removed, a free-standing shape is left.

Net- and near-net-shape (NNS) techniques facilitate the fabrication of parts that is not practical by other means. Freestanding net-shape ion engines have been manufactured from tungsten by using load chamber, plasma-arc spray. Plasma spraying in an argon atmosphere eliminates oxidation of reaction materials, such as tungsten. Precision Al_2O_3 tubes (0.75 mm) wall thickness, 75 mm diameter, and 1.2 m length would be difficult, if not impossible, to fabricate by casting and grinding; however, they have been successfully fabricated by thermal-spray net-shape techniques. On the other extreme, multilayer ceramic tubes with 1-mm inside diameter have been made to join blood vessels.

Ceramic coatings are applied to medical instruments used for endoscopic and other forms of minimal invasive surgery.

Polymer Coatings

Polymeric coatings designed for corrosion protection are usually tougher and are applied in heavier films than are appearance coatings. Requirements of such coatings are much more stringent: They must adhere well to the substrate and must not chip easily or degrade from heat, moisture, salt, or chemicals.

Environmental factors also drive the technology behind polymer coatings replacing chromium and cadmium coatings. This is partly due to increasing concern about heavy metals. Also, automakers must now contend with acid rain in addition to salt spray, and polymers surpass chromium and cadmium in acid rain resistance.

Acrylics and alkyds are widely used for farm equipment and industrial products requiring good corrosion protection at a moderate cost. Alkyd resins, particularly, play a major role in maintenance painting because of their good weathering characteristics and ease of application with low-cost, low-toxicity solvents. Alkyd paints are also relatively high in solids, permitting good buildup of a paint film with a minimum number of coats.

Silicone modification of organic resins improves overall weatherability and durability. Compared to organic coatings in general, silicones have greater heat stability, longer life, better resistance to deterioration from sunlight and moisture, and greater biological and chemical inertness.

For optimum weatherability, silicone content should be 25%–30%. Performance of the waterborne formulations is proving to be almost identical to that of the solvent-based coatings.

For coatings requiring higher heat resistance, silicone resins can be used alone for the paint vehicles, or they can be blended with various organic resins. These finishes are used on space heaters, clothes dryers, and barbecue grills. Similar formulations are used on smoke-stacks, incinerators, boilers, and jet engines. Performance of formulations containing ceramic frits approaches that of ceramic materials.

Polyurethane enamels are characterized by excellent toughness, durability, and corrosion resistance. These thermosetting materials, available in both one- and two-part formulations, cost more than the alkyds and acrylics.

Urethane chemistry is versatile enough to provide a hard, durable, environmentally resistant film, a tough, elastomeric coating, or a surface somewhere between. Urethanes have traditionally been available as solvent-based coatings containing 25%–45% solids, but environmental concerns have prompted manufacturers to also supply them in high solids, 100% solids, and waterborne formulations.

Coating thickness of polyurethanes ranges from about 2 mil for average requirements to as much as 30 mil for applications requiring impact and/or abrasion resistance as well as corrosion resistance. Typical uses are on conveyor equipment, aircraft radomes, tugboats, road-building machinery, and motorcycle parts. Abrasion-resistant coatings of urethanes are applied on railroad hopper cars, and linings are used in sandblasting cabinets and slurry pipes.

Epoxy finishes have better adhesion to metal substrates than do most other organic materials. Epoxies are attractive economically because they are effective against corrosion in thinner films than are most other finishing materials. They are often used as primers under other materials that have good barrier properties but marginal adhesive characteristics.

Coating thicknesses can vary from 1 mil for light-duty protection to as much as 20 mil for service involving the handling of corrosive chemicals or abrasive materials. Performance of epoxies is limited in the heavier thickness, however, because they are more brittle than other organic materials.

Nylon 11 coatings provide attractive appearance as well as protection from chemicals, abrasion, and impact. Applied by electrostatic spray in thicknesses from 2.5 to 8 mil, nylon coatings are used on office and outdoor furniture, hospital beds, vending-machine parts, and building railings. Heavier coatings—to 50 mil—are applied by the fluidized-bed method and are used to protect dishwasher baskets, food-processing machinery, farm and material-handling equipment, and industrial equipment such as pipe, fittings, and valves.

Fluorocarbons are more nearly inert to chemicals and solvents than all other polymers. The most effective barriers among the fluorocarbons for a variety of corrosive conditions are PFA, PTFE, ECTFE, FEP, and PVDF.

Ethylene-chlorotrifluoroethylene (ECTFE) is a member of the fluoropolymer family of resins. This high-temperature coating provides corrosion resistance and mechanical and electrical qualities up to 149°C. It is easy to apply and has excellent release and low-friction properties. Multiple layers of ECTFE can be applied up to 100 mil. Although more expensive than other powders, its performance often justifies a higher cost. ECTFE has a smooth surface as applied and is therefore used in water handling systems to minimize bacterial buildup.

Fluorinated ethylene propylene (FEP) is a soft fluoropolymer coating similar to PTFE and PFA. It has the best release properties among powder coatings. The corrosion-resistant qualities of FEP are better than PTFE, but FEP does not stand up to high temperatures as well.

Perfluoroalkoxy (PFA) is another member of the fluoropolymer family that resists corrosion and has better release and nonwetting qualities than PTFE. With wide temperature limits, PFA can be used in applications ranging from cryogenic levels to 260°C. It is typically used for coating molding cavities, and this food-grade-quality powder can also be used for baking surfaces.

Polytetrafluoroethylene (PTFE) is a soft and waxy material that has release properties similar to PFA. The high-temperature coating protects against corrosion in environments reaching 260°C.

However, its softness limits it to nonabrasive and moderately abrasive applications.

Polyvinylidene fluoride (PVDF) is the hardest powder coating with qualities similar to PPS, making it ideal for high-load and higher-modulus applications. The coating works well in corrosive environments for components in pulp mills, waste treatment plants, and petrochemical facilities. Once applied, PVDF coatings can be removed only with heat. The coating has a surface temperature limit of 130°C and is not commonly used for release and low-friction applications.

For impact service, PVDF and ECTFE coatings are recommended, in that order. PTFE, FEP, and PFA are also suitable, but they have a greater tendency to creep under load. For abrasive conditions, PVDF is outstanding among the fluorocarbons. Recommended for high surface temperatures—drying ovens and steam-handling equipment, for example—are PFA and PVDF. These materials are also used on engine components and welders. PVDF also has the highest compressive strength of the fluorocarbons. PTFE has the highest allowable service temperature (316°C) of the fluorocarbons.

Coatings based on PTFE are being used to reduce wear in the US automotive industry. Fluoropolymer coatings prevent binding and galling in disk brake systems at temperatures over 100°C. PTFE is also used as a dry lubricant. In addition, PTFE can be used as a coating on automotive fasteners, and a new process uses PTFE to prevent seizure in valve springs. This process is FluoroPlate impingement, a process whereby a mixture of inorganic and organic particles bombard the spring surface, thus relieving internal stresses and reducing surface flaws. The coating also helps the springs to repel oil.

A new class of coating—an alloy of fluoropolymer and other resins—has a different viscosity behavior than that of the earlier organics. Viscosity of “fastener-class” coating resins decreases sharply as film shear increases (as in application by the dip/spin process). Then, when the spinning basket stops, viscosity returns almost instantaneously to its original value. Thus, when applied to the dip/spin process, the coating clings to sharp edges, threads, and points.

Film thickness typically ranges from 0.5 to 0.7 mil, but formulations can be adjusted to provide films of 0.3–0.4 mil for parts with fine threads or other intricate features. Not only do these extremely tough coatings provide a more uniform barrier to corrosives, but they are also based on polymers that are inherently stable in the presence of a wide spectrum of acids, bases, and aqueous solutions.

Combination coatings blend the advantages of anodizing or hard-coat platings with the controlled infusion of low-friction polymers and/or dry lubricants. The coatings become an integral part of the top layers of metal substrates, providing increased hardness and other surface properties.

These coatings are different for each class of metals. For example, a Tufam coating for aluminum combines the hardness of Al_2O_3 and the protection of a fluorocarbon topcoat to impart increased hardness, wear and corrosion resistance, and permanent lubricity.

In the multistep process, the surface is first converted to Al_2O_3 . Submicron particles of PTFE are then fused into the porous anodized surface, forming a continuous plastic/ceramic surface that does not chip, peel, or delaminate. The coating is claimed to have greater abrasion resistance than case-hardened steel or hard chromium plate.

Another proprietary coating that penetrates PTFE into precision hardcoat anodizing is Nituff. The coating achieves a self-curing, self-lubricating surface with low friction, high corrosion resistance, and dielectric properties superior to ordinary hardcoat anodizing. It is used extensively in aerospace, textile, food processing, packaging, and other industries, where it allows manufacturers to benefit from the lightweight and easy machinability of aluminum enhanced by the durability, cleanliness, and dry lubrication of the Nituff surface.

Other proprietary combination coatings have been developed for steel, stainless steel, copper, magnesium, and titanium that provide similar surface improvement. Coatings are also available that enhance specific properties such as lubricity, corrosion resistance, or wear resistance.

Powder Coatings

Powder coatings are generally much thicker than fluids, typically greater than 5 mil compared to 1 or 2 mil for fluids. Powders commonly protect substrates from corrosion and erosion wear, or provide release or aesthetic qualities. Fluid coatings, in contrast, are preferred for friction, abrasion, and spalling wear—corrosion applications that require low friction and release.

In addition to performance attributes, powder coatings also provide processing advantages over fluids. Powders are environmentally friendly because they do not contain volatile organic compounds (VOCs) that attack the ozone layer.

The powder coating combines properties of both plastics and paints. The coatings are manufactured using typical plastics-industry equipment. They are first sent through a melt-mix extruder and then ground. When applied as a coating, however, the powder becomes a coating film that is exactly like paint.

These coatings have been developed in response to pressures to reduce VOC emissions, which have increased over the past few years. Overspray from liquid paints contains solvents that are released into the atmosphere. Even with recovery systems, some volatile components escape. Powder coatings, on the other hand, are completely recyclable. Overspray can be collected easily and reused. If a small amount becomes too contaminated for recycling, safe disposal techniques are available.

Powder coatings also show promise as a substitute for clear coats in the automotive industry. Present solvent-based paints could be replaced by a clear powder coating that cures at roughly the same temperature as conventional paints. Powder coatings may also replace the baked-on porcelain enamel used for appliance parts. Washer and dryer lids are now powder-coated in industry.

Applications are not all that is new, however. Materials have changed. The majority of powder coatings have relied on either an epoxy or polyester resin base. Acrylics, however, are becoming more important, and other possible bases include nylon, vinyl, and various fluoropolymers.

Two processes for applying coatings have undergone refinements. With electrostatic spraying, the most popular method, powder is given a charge and sprayed onto electrically grounded parts. Baking them completes the cure. Nonconductive parts must be primed or heated to provide them with more electrostatic attraction.

In the fluid-bed process, air passes through a porous membrane at the bottom of a tank and aerates the powder so that it swirls around in the tank. A part is then heated and dipped into the tank, so that the powder melts on the surface. This process is used for thick-film protection coatings, and is suitable only for metal parts that can retain heat long enough to be coated.

Liquid Layers

Despite strict governmental restrictions that continue to thwart the amount of VOCs released into the atmosphere, the use of high-performance fluid coatings remains widespread. Unlike powder coatings, fluids can be applied in films as thin as 0.2 mil without affecting their integrity. Powder coatings, in contrast, require more clearance between components to accommodate thicknesses greater than 5 mil.

FIGURE C.1 A closer look at coatings. (From *Machine Designs*, September 10, 1998, p. 103. With permission.)

Another advantage of fluid coatings is that manufacturers can apply them by conventional and electrostatic spray processes, as well as by brush and dip methods. This is particularly important for components with deep recesses that are difficult to coat with powders using electrostatic means because the charged particles adhere to the outer edge of the recess. Probe-spray systems, in turn, are much more efficient for covering recesses with fluid coatings.

Following is a summary of the fluid coatings that are commonly used to protect engineering materials; see Figure C.1.

Matrix coatings have the highest mechanical properties, such as tensile strength and wear resistance, among fluid coatings. They consist of one or more polymer binders (PPS, polyimide) combined with a dry lubricant such as PTFE, PFA, MoS₂, or graphite. When applied, the dispersion of this composite mixture consists of lubricant evenly distributed within the binder. Typical applications include large-thread fasteners, actuators, pistons, bearings, impellers for mixers and superchargers, and rotating and sliding powder-metal components.

Stratified coatings also consist of binders and lubricants; however, their formulation keeps most of the low-friction, high-release agent on the bearing surface of the coating. With lubricant segregated to the outer surface, the top layer of stratified coatings is softer and has lower mechanical properties than matrix coatings. However, this concentration of lubricant improves release qualities, and with certain fluoropolymers, the coatings protect substrates from corrosion. Typical applications include components used in photocopiers, valves, and fuel-handling systems.

Hybrids are a new class of coatings that have greater strength than both powders and matrix-fluid coatings. To boost strength, the films are formulated with either internal or external reinforcements.

Internally reinforced coatings use microfilaments to provide a mechanical structure inside the film, acting in much the same way that rebar strengthens concrete structures. The overlapping filaments produce a film that has a wear limit that exceeds conventional measurement methods. Engineers typically use these coatings in applications with high loads such as cutting blades.

Externally reinforced coatings combine a rigid substrate such as stainless steel with a conventional high-release fluid coating

containing a low-friction release agent such as high percentages of PTFE. The films consist of two layers. The first is a continuous layer of flame-sprayed stainless steel. Manufacturers then cover the stainless steel with a thick topcoat of low-friction fluid to create a total film thickness of 1–1.4 mil. The topcoat fills the depressions and smooths over rough spots on the flame-sprayed metal coat.

Under high loads or extreme wear, the topcoat may wear away, exposing the substrate material. However, because the fluid coat remains in the asperities of the base metal, the composite coating maintains a low-friction surface while the steel helps resist wear. Typical applications are large locking and fastening mechanisms, tumblers, agitators, and parts subjected to high abrasive wear.

Conformal Coatings

Printed circuit board (PCB) assemblies used in avionics, marine, automotive, and military applications generally perform in environments affected by heat, moisture, industrial pollutants, manual handling, and process residues, which typically magnifies such effects.

The PCB designer must determine if and how the assembly must be protected with a worst-case environment in mind. Consequences ranging from malfunction to product failure will devolve from this decision. Other factors include feasibility and cost of implementation of such protection, but the designer will have several options: reducing circuit sensitivity through designed signal characteristics, increasing conductor spacing, and using buried vias. Other protective options include sealing the circuit in a box pressurized with inert gas or in a polymer via potting or molding, or employing an electrically insulating barrier between conductors and the ambient environment.

Using a polymeric-film barrier for board protection is the most common and practical approach. There are, however, limitations and peculiarities accompanying the two categories of coatings:

1. Bare-board coatings, or “permanent soldermasks,” are applied during the board fabrication process as liquids or dry films over conductive finishes or bare copper, and polymerized (cured) either by heat or ultraviolet light.
2. Assembly coatings offer protective coverage against water in the form of atmospheric humidity and condensation. They are commonly referred to as “conformal” coatings, implying compliance of the film to the contour line of the assembly. However, this term may be a misnomer, since newer application techniques permit only specific areas be coated to eliminate the cost of masking.

The use of conformal coating materials is provided in four basic material types (acrylic, epoxy, silicone, and urethane resins) for liquid-applied coatings, and one (paraxylylene) for vapor deposition. As a result, a coating must be selected on the basis of electrical, thermal, mechanical, and other pertinent properties as dictated by requirements for circuit performance and characteristics, type and degree of environmental exposure, and consequences of failure.

Coaxing

Improvement of the fatigue strength of a specimen by the application of a gradually increasing stress amplitude, usually starting below the fatigue limit.

Cobalt

Cobalt (symbol Co) is a lustrous, silvery-blue metallic chemical element, resembling nickel but with a bluish tinge instead of the yellow

of nickel. It is rarer and costlier than nickel and its price has varied widely in recent years. Although allied to nickel, it has distinctive differences. It is more active chemically than nickel. It is dissolved by dilute H_2SO_4 , HNO_3 , or HCl acids, and is attacked slowly by alkalis. The oxidation rate of pure cobalt is 25 times that of nickel. Its power of whitening copper alloys is inferior to that of nickel, but small amounts in Ni–Cu alloys will neutralize the yellowish tinge of the nickel and make them whiter. The metal is diamagnetic like nickel, but has three times the maximum permeability. Like tungsten, it imparts red-hardness to tool steels. It also hardens alloys to a greater extent than nickel, especially in the presence of carbon, and can form more chemical compounds in alloys than nickel.

Its chemical properties resemble, in part, those of both nickel and iron. Cobalt has the metal with the highest Curie temperature (1121°C) and the lowest allotropic transformation temperature (399°C). Below 421°C , cobalt is close-packed hexagonal; above, it is face-centered cubic.

Properties

Cobalt has a specific gravity of 8.756, a melting point of 1495°C , 85 Brinell hardness, and an electrical conductivity about 16% that of copper. The ultimate tensile strength of pure cast cobalt is 234 MPa, but with 0.25% carbon it is increased to 427 MPa. Strength can be increased slightly by annealing and appreciably by swaging or zone refining. The metal is used in tool-steel cutters, in magnet alloys, and high-permeability alloys, and as a catalyst, and its compounds are used as pigments and for producing many chemicals.

The natural cobalt is cobalt-59, which is stable and nonradioactive, but the other isotopes from 54 to 64 are all radioactive, emitting beta and gamma rays. Most have very short life except cobalt-57, which has a half-life of 270 days, cobalt-56 with a half-life of 80 days, and cobalt-58 with a half-life of 72 days. Cobalt-60, with a half-life of 5.3 years, is used for radiographic inspection. It is also used for irradiating plastics, and as a catalyst for the sulfonation of paraffin oils because the gamma rays cause the reaction of SO_2 and liquid paraffin. Co 60 emits gamma rays of 1.1–1.3 MeV energy, which gives high penetration for irradiation. The decay loss in a year is about 12%, the cobalt changing to nickel.

The best-known cobalt alloys are the cobalt-base superalloys used for aircraft turbine parts. The desirable high-temperature properties of low creep, high stress-rupture strength, and high thermal-shock resistance are attributed to the allotropic change of cobalt to a face-centered cubic structure at high temperatures. Besides containing 36%–65% cobalt, usually more than 50%, most of these alloys also contain about 20% chromium for oxidation resistance and substantial amounts of nickel, tungsten, tantalum, molybdenum, iron, and/or aluminum, and small amounts of still other ingredients. Carbon content is in the 0.05%–1% range. These alloys include L-605; S-816; V-36; WI-52; X-40; J-1650; Haynes 21 and 151; AiResist 13, 213, and 215; and MAR-M 302, 322, and 918. Their 1000 h stress-rupture strengths range from about 276 to 483 MPa at 649°C and from about 28 to 103 MPa at 982°C . Cobalt is also an important alloying element in some nickel-base superalloys, other high-temperature alloys, and alloy steels. Besides tool steels, the maraging steels are a good example. Although cobalt-free grades have been developed, due to the scarcity of this metal at times, most maraging steels contain cobalt, as much as 12%. Cobalt is also a key element in magnet steels, increasing residual magnetism and coercive force, and in nonferrous-base magnetic alloys.

An important group of cobalt alloys is the stellites. They contain chromium and various other elements such as tungsten, molybdenum, and silicon. The extremely hard alloy carbides in a fairly hard matrix give excellent abrasion and wear resistance and are used as hard-facing alloys and for aircraft jet engine parts.

C

The interesting properties of cobalt-containing permanent, soft, and constant-permeability magnets are a result of the electronic configuration of cobalt and its high curie temperature. In addition, cobalt in well-known Alnico magnet alloys decreases grain size and increases coercive force and residual magnetism.

Cobalt is a significant element in many glass-to-metal sealing alloys and low-expansion alloys. One iron-base alloy containing 31% nickel and 5% cobalt provides a lower CTE than the iron–36% nickel alloy called Invar, and is less sensitive to variations in heat treatment. Co–Cr alloys are used in dental and surgical applications because they are not attacked by body fluids. Alloys named Vitallium are used as bone replacements and are ductile enough to permit anchoring of dentures on neighboring teeth. They contain about 65% cobalt.

Cobalt is a necessary material in human and animal metabolism, and is used in fertilizers.

Applications

The major uses of cobalt are in cobalt-base and cobalt-containing materials for high-temperature alloys, permanent magnets, and steels. In addition, cemented carbides, which are considered cutting tools, are used in balls for ballpoint pens and high-temperature ball bearings.

The hard-facing alloys are useful because of their resistance to corrosion, abrasion, and oxidation at high temperatures for plowshares, oil bits, crushing equipment, tractor treads, rolling mill guides, knives, punches, shears, billet scrapers, valves for high-pressure steam, oil refineries, and diesel and auto engines.

The superalloys have found use as searchlight reflectors, and are also useful under the severe operating conditions of high-temperature nuclear reactors. Their superior elevated-temperature properties compensate, to some extent, for the high thermal-neutron absorption for cobalt. They are used in reactors in certain wear-resistant components as guides for control rods. In nuclear submarines, these alloys are used where severe wear in contact with seawater is encountered.

Although the main application of Alnico permanent magnets is in motors, generators, regulating devices, instruments, radar, and loudspeakers, some are used in games, novelties, and door latches.

Cobalt-containing tool and high-speed steels are also used for dies.

Cobalt Oxide

A steel-gray to blue-black powder employed as a base pigment for ceramic lasers on metal, as a colorant for glass, as a chemical catalyst. It gives excellent adhesion to metals and is valued as an undercoat for vitreous enamels. It is the most stable blue, as it is not changed by ordinary oxidizing or reducing conditions. It is also one of the most powerful colorants for glass, 1 part in 20,000 parts of a batch giving a distinct blue color. Cobalt oxide is produced from the cobalt-nickel and pyrite ores, and the commercial oxide may be a mixture of the three oxides. *Cobaltous oxide*, CoO , is called *gray cobalt oxide* but varies from greenish to reddish. It is the easiest to reduce to the metal, and it reacts easily with silica and alumina in ceramics. *Cobaltic oxide*, Co_2O_3 , occurs in the mixture only as the unstable hydrate, and it changes to the stable *black cobalt oxide*, or *cobalto-cobaltic oxide*, Co_3O_4 on heating. Above about 1652°F (900°C) this oxide loses oxygen to form cobaltous oxide.

Cockling/Cockles

The wavy edge of rolled sheet and plate.

Cocoa

In *fretting wear*, a powdery form of debris, usually consisting of red iron oxides, that is expelled from a ferrous metal joint near the location where fretting wear is occurring. Also known as red mud. Fe_2O_3 is formed by fretting of iron and steel.

Co-Curing

The act of curing a composite laminate and simultaneously bonding it to some other prepared surface, or curing together an inner and outer tube of similar or dissimilar fiber–resin combinations after each has been wound or wrapped separately. See also *secondary bonding*.

COD Crack Opening Displacement

See fracture toughness.

Coefficient

A factor defining the relationship between two components. For example, the coefficient of thermal expansion is a measure of the change in dimensions resulting from a unit change in temperature.

Coefficient of Adhesion

- (1) The ratio of the normal force required to separate two bodies to the normal load with which they were previously placed together.
- (2) In railway engineering, sometimes used to signify the coefficient of (limiting) static friction.

Coefficient of Compressibility

See *bulk modulus of elasticity*.

Coefficient of Elasticity

The reciprocal of Young's modulus in a tension test. See also *compliance*.

Coefficient of Expansion

A measure of the change in length or volume of an object, specifically, a change measured by the increase in length or volume of an object per unit length or volume.

Coefficient of Friction

The dimensionless ratio of the friction force (F) between two bodies to the normal force (N) pressing these bodies together: μ (or f) = (F/N).

Coefficient of Thermal Expansion

- (1) Change in unit of length (or volume) accompanying a unit change of temperature, at a specified temperature.
- (2) The linear or volume expansion of a given material per degree rise of temperature, expressed at an arbitrary base temperature or as a more complicated equation applicable to a wide range of temperatures.

Coefficient of Wear

See *wear coefficient*.

Coercive Force

The magnetizing force that must be applied in the direction opposite to that of the previous magnetizing force in order to reduce magnetic flux density to zero; thus, a measure of the magnetic retentivity of magnetic materials.

Coextruded

An extrusion process in which two materials are extruded simultaneously so that one forms a surface layer around the other. The process is, for example, applied to tubes which require a combination of strength and corrosion resistance not obtainable in a single material.

Coextrusion Welding

A solid-state welding process which produces coalescence of the faying surfaces by heating and forcing materials through an extrusion die.

Cogging

The first reducing operation in working an ingot into a billet with a forging hammer or a forging press. See *cogging mill*.

Cogging Mill

A *blooming mill*.

Coherency

(1) The state in which the lattices of a precipitate and its surrounding parent matrix remains substantially in alignment but are distorted in the vicinity of the interface. (2) The parent phase (solvent) maintained by mutual strain and not separated by a phase boundary.

Coherent (Precipitate)

(1) An intermediate stage of precipitation, preceding formation of a distinct and separate phase, in which the lattices of the solution and the emerging precipitate are still in alignment but distorted. (2) A crystal-line precipitate that forms from solid solution with an orientation that maintains continuity between the crystal lattice of the precipitate and the lattice of the matrix, usually accompanied by some strain in both lattices. Because the lattices fit at the interface between precipitate and matrix, there is no discernible phase boundary.

Coherent Radiation

Radiation in which the phase difference between any two points in the radiation field is constant throughout the duration of the radiation.

Coherent Scattering

In materials characterization, a type of x-ray or electron scattering in which the phase of the scattered beam has a definite (not random) relationship to the phase of the incident beam. Also termed unmodified scattering. See also *incoherent scattering*.

Cohesion

(1) The state in which the particles of a single substance are held together by primary or secondary valence forces. As used in the adhesive field, the state in which the particles of the adhesive (or adherend) are held together. (2) Force of attraction between the molecules (or atoms) within a single phase. Contrast with *adhesion*.

Cohesive Blocking

The blocking of two similar, potentially adhesive faces.

Cohesive Failure

Failure of an adhesive joint occurring primarily in an adhesive layer.

Cohesive Strength

(1) The hypothetical stress causing tensile fracture without plastic deformation. (2) The stress corresponding to the forces between atoms. (3) Intrinsic strength of an adhesive. (4) Same as *technical cohesive strength*. (5) Same as *disruptive strength*.

Coil

(1) An assembly consisting of one or more magnet wire windings. (2) Rolled metal sheet or strip.

Coil Breaks

Greases or ridges in sheet or strip that appear as parallel lines across the directions of rolling and that generally extend the full width of the sheet or strip.

Coil Winding

An electrically continuous length of insulated wire wound on a bobbin/spool, or form.

Coil with Support

A filler metal package type consisting of a continuous length of electrode in coil form wound on an internal support which is a simple cylindrical section without flanges.

Coil without Support

A filler metal package type consisting of a continuous length of electrode in coil form without an internal support. It is appropriately bound to maintain its shape.

Coin Silver

An alloy containing 90% silver, with copper being the usual alloying element.

Coin Straightening

A combination coining and straightening operation performed in special cavity dies assigned to impart a specific amount of working in specified areas of a forging to relieve the stresses developed during heat treatment.

C

Coinage Metals

Metals used for currency coinage because of their availability, durability and perceived value, originally gold, silver, copper and bronze, now presumably including aluminum, nickel, etc.

Coining

(1) A closed-die squeezing operation, usually perform cold, in which all surfaces of the work are confined or restrained, resulting in a well-defined imprint of the die upon the work. (2) A *restriking* operation used to sharpen or change an existing radius or profile. (3) The final pressing of a sintered powder metallurgy compact to obtain a definite surface configuration (not to be confused with *re-pressing* or *sizing*).

Coining Dies

Dies in which the coining or sizing operation is performed.

Coke

The poorest, gray, infusible residue left after the volatile matter is driven out of bituminous coal. The coal is heated to a temperature of 2192°F–2552°F (1200°C–1400°C), without allowing air to burn it, and the volatile matter expelled. The residue, which is mainly fixed carbon and ash, is a cellular mass of greater strength than the original coal. Its nature and structure make it a valuable fuel for blast furnaces, burning rapidly and supporting a heavy charge of metal without packing. Soft, or bituminous, coals are designated as coping or noncoking, according to their capacity for being converted to coke. Coal low in carbon and high in ash will produce a coke that is friable and not strong enough for furnace use, or the ash may have low-melting-point constituents that leave glassy slag in the coke. Coke is produced in the beehive and by-product ovens, or is a by-product of gas plants. Coke is also used as a fuel in cupola melting.

The fixed carbon of good coke should be at least 86%, and sulfur not more than 1%. The porosity may vary from 40% to 60%, and the apparent specific gravity should not be less than 0.8. *Foundry coke* should have an ignition point of about 1000°F (538°C), with sulfur below 0.7%, and the pieces should be strong enough to carry the burden of ore and limestone. Coke suitable for foundry use is also made from low-grade coals by reducing them to a semi-coke, or char, and briquetting, but *semi-coke* and *smokeless fuel* are generally coals carbonized at low temperatures and briquetted for household use. These fuels are sold under trade names such as *Coalite* and *Carbolux*, and they are really by-products of the chemical industry since much greater quantities of liquids and more lighter fractions in the tar are obtained in the process.

Pitch coke, made by distilling coal tar, has a high carbon content, above 99%, with low sulfur and ash, and is used for making carbon electrodes. Petroleum coke is the final residue in the distillation of petroleum and forms about 5% of the weight of the crude oil. With the sand and impurities removed, it is about 99% pure carbon and is used for molded carbon products. *Calcined coke* is petroleum coke that has been calcined at 2400°F (1316°C) to remove volatile matter. It is used for electrodes. *Carbonite* is a natural coke found in England and in Virginia. It is a coke-like mineral formed by the baking action of igneous rocks on seams of bituminous coal.

Coke Breeze

In foundry practice, fines from coke screenings, used in blacking mixes after grinding; also briquetted for cupola use.

Coke Furnace

Type of pot or crucible furnace that uses coke as a fuel.

Coke Oven

The furnace in which coal is tightly packed and heated to form coke.

Coke Oven Gas

The gas produced in the manufacture of coke. It is a mixture of carbon monoxide, methane and hydrogen plus numerous other volatile constituents.

Coke Test

In foundry practice, the first layer of coke placed in the cupola. Also the coke used as a foundation and constructing a large mold in a *flask* or *pit*.

Cold Anodizing

A process for increasing the thickness of the normal oxide film on aluminum by immersing it in cold 50% nitric acid for a few minutes. Also see *anodizing*.

Cold Bend Test

A test in which a bar of metal is bent to some specified degree as a test of ductility or, especially in the case of tests that include a weld zone, to confirm freedom from cracking. The specimen may be plain or notched. See also *bend test*.

Cold Box Process

In foundry practice, a two-part organic resin binder system mixed in conventional mixers and blown into shell or solid core shapes at room temperature. A vapor mixed with air is blown into the core, permitting instant setting and immediate pouring of metal around it.

Cold Cast

A term used, dubiously, for a technique where a metal powder such as bronze is mixed with liquid resin and poured into a mold to solidify. The resultant item is then described as Cold Cast Bronze.

Cold Chamber Machine

A diecasting machine with an injection system that is charged with liquid metal from a separate furnace. Compare with *hot chamber machine*.

Cold Chisel

A chisel or relatively short length, substantial cross section and relatively obtuse angled cutting edge for cutting materials such as metal or brick as opposed to timber. It has no handle and the flat, beveled edge, head is struck with a hammer.

Cold Coined Forging

A forging that has been restruck cold in order to hold closer face distance tolerances, sharpen corners or outlines, reduce section thickness, flatten some particular surface, or in nonheat-treatable alloys, increase hardness.

Cold Compacting

See preferred term *cold pressing*.

Cold Cracking

(1) Cracks in cold or nearly cold cast metal due to excessive internal stress caused by contraction. Often brought about when the mold is too hard or the casting is of unsuitable design. (2) A type of weld cracking that usually occurs below 400°F (205°C). Cracking may occur during or after cooling to room temperature, sometimes with a considerable time delay. Three factors combine to produce cold cracks; stress (for example, from thermal expansion and contraction), hydrogen (from hydrogen-containing welding consumables), and a susceptible microstructure (plate martensite is most susceptible to cracking, ferritic and bainitic structures least susceptible). See also *hot cracking*, *lamellar tearing*, and *stress-relief cracking*.

Cold Die Quenching

A quench utilizing cold, flat, or shaped dies to extract heat from a part. Cold die quenching is slow, expensive, and is limited to smaller parts with large surface areas.

Cold Drawing

Technique for using standard metalworking equipment and systems for forming thermoplastic sheet at room temperature.

Cold Dry Die Quenching

Same as *cold die quenching*.

Cold Etching

Development of microstructure at room temperature and below.

Cold Extrusion

See *extrusion*.

Cold Extrusion/Forming/Drawing, etc.

See Cold Work, etc. Extrusion and Drawing, etc. In some cases of the terms there is an implication of close dimensional control of the product.

Cold Finger

In materials characterization, a liquid-nitrogen-cooled cold trap used to reduce contamination levels in vacuum chambers.

Cold Flow

The distortion that takes place in polymeric materials under continuous load at temperatures within the working range of the material without a phase or chemical change.

Cold Form Tapping

Producing internal threads by displacing material rather than removing it as either the tap or the workpiece is rotated. The thread form is produced by a tool, which has neither flutes nor cutting edges, that

resembles a simple screw when viewed from the side but the end view shows that both the major and minor diameters have irregular contours for displacing the work material.

Cold Forming

See *cold working*.

Cold Galvanizing

Painting with zinc rich paint or a similar immersion process in an attempt to obtain the protection offered by hot dip or electrogalvanizing. The coating must have good adhesion and provide electrical continuity between zinc particles and the underlying steel if any cathodic protection is to be obtained. The term has also been used of electrogalvanizing although this latter term is normally to be preferred, if only because of the likely superior protection compared with a paint or similar film.

Cold Hardening—Natural Aging

See *precipitation hardening*.

Cold Heading

(1) Working metal at room temperature such that the cross-sectional area of a portion or all of the stock is increased. (2) Cold forging the heads of bolts by an upsetting process. See also *heading* and *upsetting*.

Cold Hearth Melting

The use of a furnace with a water cooled hearth, usually copper, on which to melt materials to avoid contamination by refractories.

Cold Inspection

A visual (usually final) inspection of forgings for visible imperfections, dimensions, weight, and surface condition at room temperature. The term may also be used to describe certain nondestructive tests such as magnetic-particle, dye-penetrant, and sonic inspection.

Cold Isostatic Pressing

Forming technique in which high fluid pressure is applied to a powder (metal or ceramic) part at ambient temperature. Water or oil is used as the pressure medium.

Cold Joint (Soldered or Brazed)

A joint with inadequate bonding resulting from insufficient heating of the parent components. See also *dry joint*.

Cold Junction

The cold end datum point of the pair of wires forming a thermocouple.

Cold Lap

(1) Wrinkled markings on the surface of an ingot or casting from incipient freezing of the surface and too low a casting temperature.

(2) A flaw that results when a workpiece fails to fill the die cavity during the first forging. A seam is formed as subsequent dies force metal over this gap to leave a seam on the workpiece surface. See also *cold shut*.

Cold Mill

A mill for cold rolling of sheet or strip.

Cold Parison Blow Molding

A plastic forming technique in which parisons are extruded or injection molded separately and then stored for subsequent transportation to the blow molding machine for blowing. See also *blow molding*.

Cold Pressing (Plastics)

A bonding operation in which a plastic assembly is subjected to pressure without the application of heat.

Cold Pressing (Powder Metallurgy)

Forming a powder metallurgy compact at a temperature low enough to avoid *sintering*, usually room temperature. Contrast with *hot pressing*.

Cold Rolled Sheets

A metal mill product produced from a hot-rolled pickled coil that has been given substantial cold reduction at room temperature. The resulting product usually requires further processing to make it suitable for most common applications. The usual end product is characterized by improved surface, greater uniformity in thickness, and improved mechanical properties compared with hot rolled sheet.

Cold Rolling

(1) Cold working, by rolling, of sheet, bar, etc., to affect a size change. (2) Local rolling, of surface features such as crankshaft radii, with hardened steel wheels or rollers to induce surface hardening with beneficial residual stresses.

Cold Short

Having poor ductility and hence a susceptibility to cracking during cold working operations.

Cold Shortness

Brittleness that exists in some metals at temperatures below the recrystallization temperature.

Cold Shot

(1) A portion of the surface of an ingot or casting showing premature solidification; caused by splashing of molten metal onto a cold mold wall during pouring. (2) Small globule of metal embedded in, but not entirely fused with, the casting.

Cold Shut

(1) A discontinuity that appears on the surface of cast metal as a result of two streams of liquid meeting and failing to unite. (2) A lap on the surface of a forging or billet that was closed without fusion

during deformation. (3) Freezing of the top surface of an ingot before the mold is full. (4) Casting defects characterized by a thin oxide film at the interface between neighboring areas solidifying in isolation. This occurs when the flow of metal is interrupted allowing surface solidification that fails to diffuse with subsequently poured metal or when molten metal flows in from two directions and the interfaces to oxidize to allow the flows to merge.

Cold Slug

The first plastic material to enter an injection mold; so-called because in passing through a sprue orifice it is cooled below the effective molding temperature.

Cold Soldered Joint

A joint with incomplete coalescence caused by insufficient application of heat to the base metal during soldering.

Cold Stretch

A pulling operation with little or no heat, usually on extruded filaments, to increase tensile properties of composite materials.

Cold Test

A test in which the pour point of an oil is determined.

Cold Treatment

Exposing steel to suitable subzero temperatures (-85°C or -120°F) for the purposes of obtaining desired conditions or properties such as dimensional or microstructural stability. When the treatment involves the transformation of retained austenite, it is usually followed by tempering.

Cold Trimming

The removal of flash or excess metal from a forging at room temperature in a trimming press.

Cold Welding

(1) Welding, without any heating, between two surfaces in intimate contact. In practice high pressures and very clean, oxide free surfaces are required. Also termed *adhesion*, *galling* and *seizure*. (2) The application of special procedures allowing fusion welding, in particular arc welding, without preheat and, or postheat, in circumstances where they would normally be expected. For example, alloy steels in restrained thick sections. (3) A solid-state welding process in which pressure is used at room temperature to produce coalescence of metals with substantial deformation at the weld. Compare with *hot pressure welding*, *diffusion welding*, and *forge welding*.

Cold Work

(1) Any process of plastic deformation in which the component does not recrystallize but becomes progressively harder and stronger but less ductile up to some limit. The temperature will normally be at about ambient. If it is deliberately and significantly higher, but still below the recrystallization temperature, the process may be termed warm working. (2) Permanent strain in a metal accompanied by strain hardening.

Cold Working

Deforming metal plastically under conditions of temperature and strain rate that induce *strain hardening*. Usually, but not necessarily, conducted at room temperature. Contrast with *hot working*.

Cold-Molded Plastics

Cold-molded plastics are one of the oldest of the so-called plastic materials; they were introduced in the United States in 1908. For the first time they provided the electrical engineer with materials that could be molded into more complicated shapes than could porcelain or hard rubber, providing better heat resistance than hard rubber, and better impact strength than porcelain. They could also incorporate metal inserts.

A procedure in which a plastic is shaped at room temperature and subsequently cured by baking.

General Nature and Properties

So-called cold-molded plastics are formulated and mixed by the molder (usually in a proprietary formulation). The materials fall into two general categories: inorganic or refractory materials, and organic or nonrefractory materials.

Inorganic cold-molded plastics consist of asbestos fiber filler and either an SiO_2 -lime cement or portland cement binder. Clay is sometimes added to improve plasticity. The SiO_2 -lime materials are easier to mold although they are lower in strength than the portland cement types.

In general, advantages of these materials include high arc resistance, heat resistance, good dielectric properties, comparatively low-cost, rapid molding cycles, high production with single-cavity molds (thus low tool cost), and no need for heating of molds. On the other hand, they are relatively heavy, cannot be produced to highly accurate dimensions, are limited in color, and can be produced only with a relatively dull finish. They have been used generally for arc chutes, arc barriers, supports for heating coils, underground fuse shells, and similar applications.

Organic cold-molded plastics consist of asbestos fiber filler materials bound with bituminous (asphalt, pitches, and oils), phenolic, or melamine binders. The binder materials are mixed with solvents to obtain proper viscosities, then thoroughly mixed with the asbestos, ground and screened to form molding compounds. The bituminous-bound compounds are lowest in cost and can be molded more rapidly than the inorganic compounds; the phenolic and melamine-bound compounds have better mechanical and electrical properties than the bituminous compounds and have better surfaces as well as being lighter in color. Like the inorganic compounds, organic compounds are cold-molded, followed by oven curing.

Compounds with melamine binders are similar to the phenolics, except that melamines have greater arc resistance, lower water absorption, are nontracking, and have higher dielectric strength.

Major disadvantages of these materials, again, are relatively high specific gravity, limited colors, and inability to be molded to accurate dimensions. Also, they can be produced only with a relatively dull finish.

Compounds with bituminous binders are used for switch bases, wiring devices, connector plugs, handles, knobs, and fuse cores. Phenolic and melamine compounds are used for similar applications where better strength and electrical properties are required.

An important benefit of cold-molded plastics is the relatively low tooling cost usually involved for short-run production. Most molding is done in single-cavity molds, in conventional compression-molding presses equipped for manual, semiautomatic, or fully automatic operation.

The water-fillable plastics used to replace wood or plaster of Paris for ornamental articles, such as plaques, statuary, and lamp stands, and for model making, are thermoplastic resins that cure to closed-cell lattices that entrap water. The resin powders are mixed with water and a catalyst and poured into a mold without pressure. They give finer detail than plasters, do not crack or chip, are light in weight, and the cured material can be nailed and finished like wood. Water content can be varied from 50% to 80%.

Design Considerations

Cross sections are generally heavier than hot molded materials to provide durability in handling. Taper is not usually necessary on the part, except on projecting barriers or bosses, as well as on sides of recesses or depressions. Generous fillets should always be provided. Undercuts and reentrant angles should be avoided as they will increase mold costs and reduce production rate.

In molding, a variation of ± 0.038 mm must be allowed in thickness of part. Also, because parts are cured out of the mold, dimensional tolerances cannot be held very closely.

Lettering, figures, and simple designs can be molded on surfaces; marking is usually of the raised type and is placed on recessed surfaces to prevent rubbing off.

Cold-Press Molding

A plastic molding process in which inexpensive plastic male and female molds are used with room temperature curing resins to produce accurate parts. Limited runs are possible.

Cold-Rolled Steel

Cold-rolled steels are flat steel products produced by cold-rolling hot-rolled products. The hot-rolled product is cleaned of oxide scale by pickling and passed through a cold-reduction mill to reduce and more uniformly control thickness and to enhance surface finish. Cold rolling also increases hardness, reducing ductility. Although the steel is sometimes used as rolled, it is often subsequently annealed to improve formability and then temper-rolled or roller-leveled for flatness. Cold-rolled steels are available in carbon and alloy grades as well as high-alloy grades, such as stainless steels. For plain carbon steels, carbon content is usually 0.25% maximum, often less. Quality designations include commercial quality (CQ) steel, which is produced from rimmed, capped, or semikilled steel; drawing quality (DQ), which is made from specially processed steel and is more ductile and uniform in forming characteristics; and drawing-quality special-killed (DQSK) steel, which is still more ductile and more uniform in forming characteristics. Cold-rolled structural-quality (SQ) steel refers to cold-rolled steel produced to specific mechanical properties. Bar and rod products are often cold-drawn through dies and called cold-drawn bar steel, or cold-finished in other ways and called cold-finished bar steel.

A series of SQ ultrahigh-strength steels featuring minimum tensile strength levels of between 1000 and 1400 MPa combine superior performance with low weight. Named Docol UHS, the new steels are particularly applicable to the automotive industry. Their high-energy-absorbing properties, for example, make them useful as structural members and for components used in a car's crumple zone.

Since the steel is hardened prior to leaving the factory, industries using these steels no longer require their own warm-up plants and hardening furnaces. Cutting, shaping, and welding are achieved with traditional methods. The Docol UHS series consists of three standard steels: Docol 1000 DP, Docol 1200 DP, and Docol 1400 DP. Numbers relate to maximum loads measured in megapascals, MPa.

Cold-Runner Molding

In plastic part making, a mold in which the sprue-and-runner system (the manifold section) is insulated from the rest of the mold and temperature-controlled to keep the plastic in the manifold fluid. This mold design eliminates scrap loss from sprues and runners.

Cold-Setting Adhesive

An adhesive that sets at temperatures below 20°C (68°F). See also *hot-setting adhesive*, *intermediate-temperature-setting adhesive*, and *room-temperature-setting adhesive*.

Cold-Setting Process

In foundry practice, any of several systems for bonding mold or core aggregates by means of organic binders, relying on the use of catalysts rather than heat for polymerization (setting).

Cold-Slug Well

In plastic part making, the space provided directly opposite the sprue opening in an injection mold to trap the cold slug.

Coldstream Process

In powder metallurgy, a method of producing cleavage fractures in hard particles through particle impingements in a high-velocity cold gas stream. Also referred to as *impact crushing*.

Cold-Worked Structure

A microstructure resulting from plastic deformation of the metal or alloy below its recrystallization temperature.

Collapse

Inadvertent densification of cellular plastic material during manufacture resulting from the breakdown of cell structure.

Collapsibility

The tendency of a sand mixture to break down under the pressures and temperatures developed during casting.

Collapsible Tool

A press tool that can be easily disabled.

Collar

The reinforcing metal of a nonpressure thermit weld.

Collar Oiler

A collar on a shaft that extends into the oil reservoir and carries oil into a bearing as the shaft rotates. Wipers are usually provided to direct the oil into the bearing.

Collaring (Thermal Spraying)

Adding a shoulder to a shaft or similar component as a protective confining wall for the thermal spray deposit.

Collection Efficiency

The cross-sectional area of undisturbed fluid containing particles that will ultimately impinge on a given solid surface, divided by the projected area of the solid surface. Also known as collision efficiency, capture efficiency, catchment efficiency, and impaction ratio.

Collet

A split sleeve used to hold work or tools during machining or grinding.

Colligative Properties

Properties of plastics based on the number of molecules present. Most important are certain solution properties extensively used in molecular weight characterization.

Collimate

To make parallel to a certain line or direction.

Collimated

Rendered parallel.

Collimated Roving

Roving for reinforced plastics that has been made using a special process (usually parallel wound), such that the strands are more parallel than in standard roving.

Collimation

The degree of parallelism of light rays from a given source. A light source with good collimation produces parallel light rays, whereas a poor light source produces divergent, nonparallel light rays.

Collimator

The x-ray system component that confines the x-ray beam to the required shape. An additional collimator can be located in front of the x-ray detector to further define the portion of the x-ray beam to be measured.

Collision Efficiency

See *collection efficiency*.

Collodian Replica

In metallography, a *replica* of a surface cast in nitrocellulose.

Colloid

A stable (nonsettling) finely particulate suspension of some material within a fluid host, the dimensions of the former usually being about $\pm 1 \mu\text{m}$. Fogs, smokes, foams, emulsions, sols, and gels are examples.

Colloidal

A state of suspension in a liquid medium in which extremely small particles are suspended and dispersed but not dissolved.

Colonies (Titanium)

Regions within prior- β grains with α Platelets having nearly identical orientations. In commercially pure titanium, colonies often have serrated boundaries. Colonies arise as transformation products during cooling from the β field at cooling rates that induce platelet nucleation and growth.

Colophony

See *rosin*.

Color Buffing

Producing a final high luster by buffing. Sometimes called *coloring*.

Color Center

In materials characterization, a point lattice defect that produces optical absorption bands in an otherwise transparent crystal.

Color Concentrate

A measured amount of dye or pigment incorporated into a predetermined amount of plastic. The pigmented or colored plastic is then mixed into larger quantities of plastic material to be used for molding. This mixture is added to the bulk of plastic and measured quantity in order to produce a precise, predetermined color of finished articles to be molded.

Color Filter

In metallography, a device that transmits principally a predetermined range of wavelengths. See also *contrast filter* and *filter*.

Color Temperature

The temperature in degrees Kelvin at which a blackbody must be operated to provide a color equivalent to that of the source in question. See also *blackbody*.

Colorimeter

An instrument for measuring the hue, purity, and brightness of a color.

Coloring

Producing desired colors on metal by a chemical or electrochemical reaction. See also *color buffing*.

Columbium and Alloys

One of the basic elements, columbium (Cb) is also known as niobium and occurs in the minerals columbite and tantalite. A refractory metal, it closely resembles tantalum, is yellowish-white in

color, has a specific gravity of 8.57, a melting point of 2468°C, and an electrical conductivity 13.2% relative to copper. It is quite ductile when pure or essentially free of interstitials and impurities, notably N_2 , O_2 , and H_2 , which are limited to very small amounts. Tensile properties depend largely on purity, and columbium, with a total interstitial content of 100–200 ppm, provides about 276 MPa ultimate strength, 207 MPa yield strength, 30% elongation, and 105,000 MPa elastic modulus. Drawn wire having an ultimate tensile strength of 896 MPa has been produced. The metal is corrosion resistant to many aqueous media, including dilute mineral and organic acids, and to some liquid metals, notably lithium, sodium, and NaK. It is strongly attacked, however, by strong dilute alkalis, hot concentrated mineral acids, and HFl acid. At elevated temperatures, gaseous atmospheres attack the metal primarily by oxidation even if O_2 content is low, with the attack especially severe at 399°C and higher temperatures, necessitating the use of protective coatings. Columbium tends to gall and seize easily in fabrication. Sulfonated tallow and various waxes are the preferred lubricants in forming, and carbon tetrachloride in machining. Ferro-columbium is used to add the metal to steel. Columbium is also an important alloying element in non-ferrous alloys.

Secondary Fabrication

Pure columbium is considered one of the most workable of the refractory metals, and commercially fabricated columbium can be forged, rolled, swaged, drawn, and stamped by existing commercial techniques. In the primary or mill fabrication, and ingot is hot-worked by forging or extruding, following which the surface is conditioned to remove the contaminated layer, annealed in vacuum or an inert atmosphere to obtain a recrystallized structure, and then cold-worked (with intermediate anneals, if required) by any desired technique to final shape and size. Columbium metal containing less than a total of 0.12% combined O_2 , N_2 , and carbon can be given a cold reduction of over 90% in cross-sectional area. Secondary fabrication is done cold to avoid O_2 contamination, and lubrication is used to minimize galling or sizing on the working tools.

Vapor degreasing is an effective way to remove oils or grease from columbium parts, while immersion in various hot acids can be used for surface cleaning.

Columbium Alloys

These alloys are noted mainly for their heat resistance at temperatures far greater than those that can be sustained by most metals, but protective coatings are required for oxidation resistance. Thus, they find use for aircraft turbine components and in rocket engines, aerospace reentry vehicles, and for thermal and radiation shields. Cb–Sn and Cb–Ti alloys have found use as superconductors, and Cb–1Zr, a columbium–1% zirconium alloy, as has been used for high-temperature components, liquid-metal containers, sodium or magnesium vapor-lamp parts, and nuclear applications. It has a tensile yield strength of about 255 MPa at 21°C and 165 MPa at 1093°C. Thin cold-rolled sheet of columbium alloy C-103, which contains 10% hafnium and 1% titanium, has a tensile yield strength of 648 MPa at 21°C and 172 MPa at 1093°C. After recrystallization at 1315°C, however, yield strength drops to 345 MPa at 21°C and 124 MPa at 1093°C. The room-temperature tensile properties of the 10% tungsten, 10% hafnium, 0.1% yttrium columbium alloy, known as columbium alloy C-129, are 620 MPa ultimate strength, 517 MPa yield strength, 25% elongation, and 110,000 MPa elastic modulus. Its strength falls rapidly with increasing temperatures; tensile yield

C

strength declining to about 234 MPa at 1000°C. Other columbium alloys and their principal alloying elements are Cb-752 (10% tungsten, 2.5% zirconium), B-66 (5% molybdenum, 5% vanadium, 1% zirconium), Cb-132M (20% tantalum, 15% tungsten, 5% molybdenum, 1.5% zirconium, 0.12% carbon), FS-85 (28% tantalum, 10% tungsten, 1% zirconium), and SCb-291 (10% tantalum, 10% tungsten). Typical tensile properties of columbium alloy B-66 at room temperature and 1093°C, respectively, are 882 and 448 MPa ultimate strength, 745 and 400 MPa yield strength, 12% and 28% elongation, and 105,000 and 82,700 MPa elastic modulus. Additionally, CbSe₂, is more electrically conductive than graphite and forms adhesive lubricating film. It is used in powder form with silver, copper, or other metal powders for self lubricating bearings and gears. Columbium carbide, CbC, is an extremely hard crystalline powder, which can be molded with a metal binder and sintered for use in cutting tools. The melting point is about 3800°C (6872°F). It is made by sintering columbium powder and carbon in a hydrogen furnace.

The secondary fabrication of columbium-base alloys creates a problem because of their greater strength at high temperatures and as a result are more difficult to work than the unalloyed metal. Procedures have been developed for the primary and secondary fabrication. Breakdown of the initial ingot requires higher temperatures and finish cold rolling involves more frequent annealing or, in some cases, hot rolling.

Columnar Grains/Structure

A coarse structure of parallel elongated grains formed by unidirectional growth, most often observed in castings, but sometimes seen in structures resulting from diffusional growth accompanied by a solid-state transformation.

Coma

In materials characterization, a lens aberration occurring in that part of the image field that is some distance from the principal axis of the system. It results from different magnification in the various lens zones. Extra-axial object points appear as short cone-like images with the brighter small head toward the center of the field (positive coma) or away from the center (negative coma).

Combination Die

(1) A die-casting die having two or more different cavities for different castings. (2) For forming, see *compound die*.

Combination Mill

(1) An arrangement of a continuous mill for roughing and a *guide mill* or *looping mill* for shaping. (2) A rolling mill in which the initial cogging mill is followed immediately by a further series of rolls to complete the hot rolling process.

Combination Mold

See *family mold*.

Combine Stresses

Any state of stress that cannot be represented by a single component of stress; that is, one that is more complicated than simple tension, compression, or shear.

Combined Carbon

Carbon in iron or steel that is combined chemically with other elements; not in the free state as graphite or temper carbon. The difference between the total carbon and the graphite carbon analyses. Contrast with *free carbon*.

Combined Cyanide

The cyanide of a metal-cyanide complex ion.

Combing

Lining up of reinforcing fibers.

Comet Tails (on a Polished Surface)

A group of comparatively deep unidirectional scratches that form adjacent to a microstructural discontinuity doing mechanical polishing. They have the general shape of a comet tail. Comet tails form only when a unidirectional motion is maintained between the surface being polished and the polishing cloth.

Comminution

(1) The production of fine powder by various processes including pulverizing, attrition, chemical or electrochemical techniques. (2) Breaking up or grinding an ore into small fragments. (3) Reducing metal to powder by mechanical means. (4) The act or process of reduction of powder particle size, usually but not necessarily by grinding or milling. See also *pulverization*.

Common Brass

Alloy of 63% copper and 37% zinc. The highest zinc level and hence the cheapest alloy that remains single, (alpha) phase allowing it to be cold worked.

Commutator-Controlled Welding

Spot or projection welding in which several electrodes, in simultaneous contact with the work, function progressively under the control of an electrical commutating device.

Compact (Noun)

The object produced by the compression of metal powder, generally while confined in a die.

Compact (Verb)

The operation or process of producing a compact; sometimes called pressing.

Compact Tension Specimen (CTS)

See *fracture toughness*.

Compacted Graphite Cast Iron

Cast iron having a graphite shape intermediate between the flake form typical of gray cast iron and the spherical form of fully

spherulitic ductile cast iron. An acceptable compacted graphite iron structure is one that contains no flake graphite, <20% spheroidal graphite, and 80% compacted graphite (ASTM A247, type IV). Also known as CG iron or vermicular iron, compacted graphite cast iron is produced in a manner similar to that for ductile cast iron, but using a technique that inhibits the formation of fully spherulitic graphite nodules. Typical nominal compositions of CG irons containing 3.1%–4.0% C, 1.7%–3.0% Si, and 0.1%–0.6% Mn.

Compactibility

See *compressibility*.

Compacting Crack

A crack in a powder metallurgy compact that is generated during the major phases of the pressing cycle, such as load application, load release, and ejection.

Compacting Force

The force that acts on a powder to be densified expressed in newtons or tons.

Compacting Pressure

In powder metallurgy, the specific compacting force related to the area of contact with the press punch expressed in megapascals, meganewtons per square meter, or tons per square inch.

Compacting Tool Set

See *die*.

Compaction

(1) The act of forcing particulate or granular material together (consolidation) under pressure or impact to yield a relatively dense mass or formed object. Usually followed by drying, curing, or firing in refractory or other ceramic or powder metallurgy processing. (2) In ceramics or powder metallurgy, the preparation of a compact or object produced by the compression of a powder, generally while confined in a die, with or without the inclusion of lubricants, binders, etc., and with or without the concurrent applications of heat. (3) In reinforced plastics and composites, the application of a temporary vacuum bag and vacuum to remove trapped air and compact the lay-up.

Comparison Standard

In metallography, a standard micrograph or a series of micrographs, usually taken at 75×–100×, used to determine grain size by direct comparison with the image.

Compatibility (Frictional)

In tribology, materials that exhibit good sliding behavior, including resistance to adhesive wear, are termed frictionally compatible. Under some conditions materials that are not normally considered compatible in a metallurgical sense (for example, silver and iron) may be very compatible in the frictional sense.

Compatibility (Lubricant)

In tribology, a measure of the degree to which lubricants or lubricant components can be mixed without harmful effects such as formation of deposits.

Compatibility (Metallurgical)

A measure of the extent to which materials are mutually soluble in the solid state.

Compatibility (Plastics)

The ability of two or more substances combined with one another to form a homogeneous composition having useful plastic properties; for example, the suitability of a sizing or finish for use with certain general resin types. Nonreactivity or negligible reactivity between materials and contact.

Compensating Eyepiece

In metallography, an eyepiece design for use with apochromatic objectives. They are also used to advantage with high-power (oil-immersion) achromatic objectives. Because apochromatic objectives are undercorrected chromatically, these eyepieces are overcorrected. See also *apochromatic objective*.

Compensating Leads

The electrical conductor wires between a thermocouple and the instrument measuring the e.m.f. The wire materials are selected to have the same thermoelectric characteristics as their respective thermocouple wires over the temperature range that the lead experiences. The benefits offered are that the lead can be stranded to improve flexibility and it can be of cheaper material than the thermocouple.

Complete Fusion

Fusion which has occurred over the entire base material surfaces intended for welding and between all layers and weld beads.

Complete Joint Fusion

Joint penetration in which the weld metal completely fills the groove and is fused to the base metal throughout its total thickness.

Complete Penetration

See preferred term *complete joint penetration*.

Complex Ion

An ion that may be formed by the additional reaction of two or more other ions.

Complex Modulus

The ratio of stress to strain in which each is a vector that may be represented by a complex number. May be measured in tension or flexure, compression, or shear.

Complex Shear Modulus

The vectorial sum of the shear modulus and the loss modulus.

Complex Silicate Inclusions

A general term describing silicate inclusions containing visible constituents in addition to the silicate matrix. An example is corundum or spinel crystals occurring in a silicate matrix in steel.

Complex Young's Modulus

The vectorial sum of Young's modulus and the loss modulus.

Complexation

The formation of complex chemical species by the coordination of groups of atoms termed ligands to a central ion, commonly a metal ion. Generally, the ligand coordinates by providing a pair of electrons that forms an ionic or covalent bond to the central ion. See also *chelate*, *coordination compound*, and *ligand*.

Complexing Agent

A substance that is an electron donor and that will combine with a metal ion to form a soluble complex ion.

Compliance

(1) Tensile compliance is the reciprocal of Young's modulus. Shear compliance is the reciprocal of shear modulus. The term is also used in the evaluation of stiffness and deflection. (2) The measure of the ability of a shaft or similar body to flex elastically.

Component

(1) One of the elements or compounds used to define a chemical (or alloy) system, including all phases, in terms of the fewest substances possible. (2) One of the individual parts of a vector as referred to a system of coordinates. (3) An individual functional element in a physically independent body that cannot be further reduced or divided without destroying its stated function, for example, a resistor, capacitor, diode, or transistor.

Component of Variance

A part of the total variance identified with a specified source of variability.

Composite

See *composite material*.

Composite Bearing Material

A solid material composed of a continuous or particulate solid lubricant dispersed throughout a load-bearing matrix to provide continuous replenishment of solid lubricant films as wear occurs, and effective heat transfer from the friction surface.

Composite Coating

A coating on a metal or nonmetal that consists of two or more components, one of which is often particulate in form. Example: a

cermet composite coating on a cemented carbide cutting tool. Also known as multilayer coating.

Composite Compact

A metal powder compact consisting of two or more adhering layers, rings, or other shapes of different metals or alloys with each material retaining its original identity.

Composite Electrode

A welding electrode made from two or more distinct components, at least one of which is filler metal. A composite electrode may exist in any of various physical forms, such as stranded wires, filled tubes, or covered wire.

Composite Joint

A joint in which welding is used in conjunction with mechanical joining.

Composite Material

Composite materials are based on the controlled distribution of one or more reinforcement materials in a continuous matrix. Plastics are the most common matrix materials, although metals, ceramics, and intermetallics are also used. Reinforcements include ceramics, glass, polymers, carbon, and metals. They can be in the shape of filaments, spheres, irregularly shaped particles, short fibers known as whiskers, or flat particles known as flakes.

Composites are also found in nature. Wood is a composite of cellulose fibers bonded by a matrix of natural polymers, mainly lignin. Egyptians reinforced mud with straw to make bricks. Concrete can be classified as a ceramic composite in which stones are dispersed among cement. And in the 1940s, short glass fibers impregnated with thermosetting resins, known as fiberglass, became the first composite with a plastic matrix.

In a properly designed composite, the reinforcement compensates for low properties of the matrix. Furthermore, in many cases synergism enables the reinforcing material to improve properties in the matrix. Composites also offer the capability of placing specific properties where they are needed on the part.

All these developments mean a larger and more-complicated choice of materials. This diversity has made plastics applicable to a broad range of consumer, industrial, automotive, and aerospace products. It has also made the job of selecting the best materials from such a huge array of candidates quite challenging.

Definition

Composite materials are macroscopic combinations of two or more distinct materials with a discrete and recognizable interface separating them.

Constituents and Construction

In principle, composites can be constructed of any combination of two or more materials-metallic, organic, or inorganic; but the constituent forms are more restricted. The matrix is the body constituent serving to enclose the composite and give it bulk form. Major structural constituents are fibers, particles, laminae or layers, flakes,

fillers, and matrices. They determine the internal structure of the composite. Usually, they are the additive phase.

Because the different constituents are intermixed or combined, there is always a contiguous region. It may simply be an interface, that is, the surface forming the common boundary of the constituents. An interface is in some ways analogous to the grain boundaries in monolithic materials. In some cases, however, the contiguous region is a distinct added phase, called an interphase. Examples are the coating on the glass fibers in reinforced plastics and the adhesive that bonds the layers of a laminate together. When such an interphase is present, there are two interfaces, one between the matrix and the interphase and one between the fiber and the interface.

Interfaces are among the most important yet least understood components of a composite material. In particular, there is a lack of understanding of processes occurring at the atomic level of interfaces, and how these processes influence the global material behavior. There is a close relationship between processes that occur on the atomic, microscopic, and macroscopic levels. In fact, knowledge of the sequence of events occurring on these different levels is important in understanding the nature of interfacial phenomena. Interfaces in composites, often considered as surfaces, are in fact zones of compositional, structural, and property gradients, typically varying in width from a single atom layer to micrometers. Characterization of the mechanical properties of interfacial zones is necessary for understanding mechanical behavior.

Nature and Performance

Several classification systems for composites have been developed, including classification by (1) basic material combinations, for example, metal-organic or metal-inorganic; (2) bulk-form characteristics, such as matrix systems or laminates; (3) distribution of the constituents, that is, continuous or discontinuous; and (4) function, for example, electrical or structural.

There are five classes under the classification of basic material combinations: (1) fiber composites, composed of fibers with or without a matrix; (2) flake composites, composed of flat flakes with or without a matrix; (3) particulate composites, composed of particles with or without a matrix; (4) filled (or skeletal) composites, composed of a continuous skeletal matrix filled by a second material; and (5) laminar composites, composed of layer or laminar constituents.

There is also a classification based on dimensions. The dimensions of some of the components of composite materials vary widely and overlap the dimensions of the microstructural features of common conventional materials. They range from extremely small particles or fine whiskers to the large aggregate particles or rods in reinforced concrete.

The behavior and properties of composites are determined by the composition, form and arrangements, and interaction between the constituents. The intrinsic properties of the materials of which the constituents are composed largely determine the general order or range of properties of the composite. Structural and geometrical characteristics—that is, the shape and size of the individual constituents, their structural arrangement and distribution, and the relative amount of each—contribute to overall performance. Of far-reaching importance are the effects produced by the combination and interaction of the constituents. The basic principle is that by using different constituents it is possible to obtain combinations of properties and property values that are different from those of the individual constituents.

A performance index is a property or group of properties that measures the effectiveness of a material in performing a given function. The values of performance indices for a composite differ from those of the constituents.

Fiber–Matrix Composites

Fiber–matrix composites have two constituents and usually a bonding phase as well.

Fibers

The performance of a fiber–matrix composite depends on orientation, length, shape, and composition of the fibers; mechanical properties of the matrix; and integrity of the bond between fibers and matrix. Of these, orientation of the fibers is perhaps most important.

Fiber orientation determines the mechanical strength of the composite and the direction of greatest strength. Fiber orientation can be one-dimensional, planar (two-dimensional), or three-dimensional. The one-dimensional type has maximum composite strength and modulus in the direction of the fiber axis. The planar type exhibits different strengths in each direction of fiber orientation; and the three-dimensional type is isotropic but has greatly decreased reinforcing values. The mechanical properties in any one direction are proportional to the amount of fiber by volume oriented in that direction. As fiber orientation becomes more random, the mechanical properties in any one direction become lower.

Fiber length also impacts mechanical properties. Fibers in the matrix can be either continuous or short. Composites made from short fibers, if they could be properly oriented, could have substantially greater strengths than those made from continuous fibers. This is particularly true of whiskers, which have uniform high tensile strengths. Both short and long fibers are also called chopped fibers. Fiber length also has a bearing on the processibility of the composite. In general, continuous fibers are easier to handle but have more design limitations than short fibers.

Bonding

Fiber composites are able to withstand higher stresses than their individual constituents because the fibers and matrix interact, resulting in redistribution of the stresses. The ability of constituents to exchange stresses depends on the effectiveness of the coupling or bonding between them. Bonding can sometimes be achieved by direct contact of the two phases, but usually a specially treated fiber must be used to ensure a receptive adherent surface. This requirement has led to the development of fiber finishes, known as coupling agents. Both chemical and mechanical bonding interactions occur for coupling agents.

Voids (air pockets) in the matrix are one cause of failure. A fiber passing through the void is not supported by resin. Under load, the fiber may buckle and transfer stress to the resin, which readily cracks. Another cause of early failure is weak or incomplete bonding. The fiber–matrix bond is often in a state of shear when the material is under load. When this bond is broken, the fiber separates from the matrix and leaves discontinuities that may cause failure. Coupling agents can be used to strengthen these bonds against shear forces.

Reinforced Plastics

Probably the greatest potential for lightweight high-strength composites is represented by the inorganic fiber-organic matrix composites, and no composite of this type has proved as successful as glass-fiber-reinforced composites. As a group, glass-fiber-plastic composites have the advantages of good physical properties, including strength, elasticity, impact resistance, and dimensional stability; high strength-to-weight ratio; good electrical properties; resistance to chemical attack and outdoor weathering; and resistance to moderately high temperatures (about 260°C).

A critical factor in reinforced plastics is the strength of the bond between the fiber and the polymer matrix; weak bonding causes fiber

pullout and delamination of the structure, particularly under adverse environmental conditions. Bonding can be improved by coatings and the use of coupling agents. Glass fibers, for example, are treated with silane (SiH_4) for improved wetting and bonding between the fiber and the matrix.

Generally, the greatest stiffness and strength in reinforced plastics are obtained when the fibers are aligned in the direction of the tension force. Other properties of the composite, such as creep resistance, thermal and electrical conductivity, and thermal expansion, are anisotropic. The transverse properties of such a unidirectionally reinforced structure are much lower than the longitudinal. Seven mechanical and thermal properties are of direct interest in assessing the potential of a new composite: density, modulus, strength, toughness, thermal conductivity, expansion coefficient, and heat capacity; others, such as fracture toughness and thermal diffusivity, are calculated from them.

Tailoring Properties

The ideal way to develop a product made of composites is to model and analyze it extensively by computer before a prototype is built. But this is difficult because most computer programs were developed for metals and do not work well with composites.

Many new applications for composites are structural. Since the objective of structural parts generally is to maximize strength-to-weight ratios, a key design objective is to optimize configurations as well as materials.

After a design is defined, manufacturing is the next challenge. Building a single part normally is not technically taxing. The trick comes in fabricating composite parts reliably in mass production. Manufacturing operations tend to be expensive because fabrication is labor-intensive, and the labor must be skilled.

The processes for fabricating composites also may produce built-in defects. For this reason, provisions for nondestructive testing should go hand-in-hand with fabrication. Unfortunately, available methods for nondestructive testing often leave a lot to be desired.

All these problems are being combated. Better guidelines are being developed to help designers select a composite and define its shape. Software is being developed to cope with the analytical complexities posed by composites and to help with the optimization process. Finally, major efforts are being exerted to automate fabrication processes and refine nondestructive testing operations.

Thermoplastic Composites

No longer is product design a constraint to the property limits and performance characteristics of unmodified grades of resins. Thermoplastics that are reinforced with high-strength, high-modulus fibers provide dramatic increases in strength and stiffness, toughness, and dimensional stability. The performance gain of these composites usually more than compensates for their higher cost. Processing usually involves the same methods used for unreinforced resins.

Glass and Mineral Fibers

Glass fibers used in reinforced compounds are high-strength, textile-type fibers, coated with a binder and coupling agent to improve compatibility with the resin and a lubricant to minimize abrasion between filaments. Glass-reinforced thermoplastics are usually supplied as ready-to-mold compounds. Molded products may contain as

little as 5% and as much as 60% glass by weight. Pultruded shapes (usually using a polyester matrix) sometimes have higher glass contents. Most molding compounds, for best cost/performance ratios, contain 20%–40% glass.

Practically all thermoplastic resins are available in glass-reinforced compounds. Those used in largest volumes are nylon, polypropylene, polystyrene, ABS, and SAN, probably because most experience with reinforced thermoplastics has been based on these resins. The higher-performance resins—PES, PEI, PPS, PEEK, and PEK, for example—are also available in glass-fiber-reinforced composites, and some with carbon or aramid fibers as well.

Glass-fiber reinforcement improves most mechanical properties of plastics by a factor of two or more. Tensile strength of nylon, for example, can be increased from about 70 MPa to over 210 MPa, and deflection temperature to almost 260°C, from 77°C. A 40% glass-fortified acetyl has a flexural modulus of 1.89 MPa, a tensile strength of 150.5 MPa, and a deflection temperature of 168°C. Reinforced polyester has double the tensile and impact strength and four times the flexural modulus of the unreinforced resin.

Also improved in reinforced compounds are tensile modulus, dimensional stability, hydrolytic stability, and fatigue endurance.

Fiber reinforcement of a resin always changes its impact behavior and notch sensitivity. The change may be in either direction, depending on the specific resin involved. But even when the change is an improvement, these properties may not be high enough for certain demanding applications. This need has led to the development of impact-modified compounds—specifically, nylon 6 and 6/6 alloys, a nylon 6/6 copolymer, and a polypropylene copolymer—with up to 50% improvement over reinforced unmodified compounds. Although the impact properties of a glass-reinforced compound are not always superior to those of the unreinforced compound, the reinforced modified compounds are always superior to the reinforced unmodified grades.

Applications

Molded glass-reinforced and mineral-reinforced plastics are used in a broad range of structural and mechanical parts. For example, glass-reinforced nylon, because of its strength and stiffness, is used in gears and automotive under-the-hood components, whereas mineral-reinforced nylon is used in housings and body parts because it is tougher and has low warpage characteristics. Polypropylene applications include automotive air-cleaner housings and dishwasher tubs and inner doors. Polycarbonate is used in housings for water meters and power tools. Polyester applications include motor components—brush holders and fans—high-voltage enclosures, television tuner gears, electrical connectors, and automobile exterior panels.

Advanced Composites

Advanced composites comprise structural materials that have been developed for high-technology applications, such as airframe structures, for which other materials are not sufficiently stiff. In these materials, extremely stiff and strong continuous or discontinuous fibers, whiskers, or small particles are dispersed in the matrix. A number of matrix materials are available including carbon, glass, ceramics, metals, and polymers. Advanced composites possess enhanced stiffness and lower density compared to fiberglass and conventional monolithic materials. Although composite strength is primarily a function of the reinforcement, the ability of the matrix to support the fibers or particles and to transfer load to the reinforcement, is equally important. Also, the matrix frequently dictates service conditions, for example, the upper temperature limit of the composite.

Reinforcements

Continuous filamentary materials that are used as reinforcing constituents in advanced composites are carbonaceous fibers, organic fibers, inorganic fibers, ceramic fibers, and metal wires. Reinforcing inorganic materials are used in the form of discontinuous fibers and whiskers.

Carbon and graphite fibers offer high modulus and the highest strength of all reinforcing fibers. These fibers are produced in a pyrolysis chamber from three different precursor materials—rayon, polyacrylonitrile (PAN), and pitch. High-modulus carbon fibers are available in an array of yarns and bundles of continuous filaments (tows) with differing moduli, strengths, cross-sectional areas, twists, and plies.

Almost any polymer fiber can be used in a composite structure, but the first one with high-enough tensile modulus and strength to be used as a reinforcement in advanced composites was an aramid, or aromatic polyamide, fiber. Aramid fibers have been the predominant organic reinforcing fiber; graphite is a close second.

The most important inorganic continuous fibers for reinforcement of advanced composites are boron and SiC, both of which exhibit high stiffness, high strength, and low density. Continuous fibers are made by chemical vapor deposition (CVD) processes. Other inorganic compounds that provide stiff, strong discontinuous fibers that predominate as reinforcements for metal–matrix composites (MMC) are SiC, Al₂O₃, graphite, Si₃N₄, TiC, and boron carbide.

Polycrystalline Al₂O₃ is a commercial continuous fiber that exhibits high stiffness, high strength, high melting point, and exceptional resistance to corrosive environments. One method to produce the fibers is dry spinning followed by heat treatment.

Whiskers are single crystals that exhibit fibrous characteristics. Compared to continuous or discontinuous polycrystalline fibers, they exhibit exceptionally high strength and stiffness. SiC whiskers are prepared by chemical processes or by pyrolysis of rice hulls. Whiskers made of Al₂O₃ and Si₃N₄ are also available. Particulates vary widely in size, characteristics, and function, and since particulate composites are usually isotropic, their distribution is usually random rather than controlled.

Organic–Matrix Composites

In many advanced composites the matrix is organic, but metal matrices are also used. Organic matrix materials are lighter than metals, adhere better to the fibers, and offer more flexibility in shaping and forming. Ceramic–matrix composites (CMC), carbon–carbon composites (C–C), and intermetallic–matrix composites (IMC) have applications where organic or metal matrix systems are unsuitable.

Materials

Epoxy resins have been used extensively as the matrix material. However, bismaleimide (BMI) resins and polyimide (PI) resins have been developed to enhance in-service temperatures. Thermoplastic resins, PEK, and polyphenylene sulfide (PPS) are in limited use.

The continuous reinforcing fibers for organic matrices are available in the forms of monofilaments, multifilament fiber bundles, unidirectional ribbons, roving (slightly twisted fiber), and single-layer and multilayer fabric mats. Frequently, the continuous reinforcing fibers and matrix resins are combined into a nonfinal form known as a prepreg.

The matrix material generally governs the service temperature. For PMCs, thermosets are the common matrix material. *Epoxy*, the most widely used, allows service temperatures up to about 300°F (149°C). *Bismaleimide* (BMI), which has replaced epoxy to some

extent in military aircraft applications, permits use to about 350°F (177°C). *Cycrom 5250-4*, *5260*, and *5270-1* are BMIs from Cytec Fiberite. The 5250-4 and toughened 5260 have service temperatures to about 350°F (177°C), the 5270-1 to as high as 450°F (232°C). *Cycrom 5250-4 RTM* is for resin-transfer-molding applications.

Polyimide, with a maximum service temperature of at least 500°F (260°C), is used to a much more limited extent. The principal load-bearing elements, however, are the fibers, typically continuous, contained by the matrix. These include *aramid*, *Kevlar* mainly, *boron*, *glass*, and *graphite*. PMCs are lightweight, strong, and rigid, thus providing high strength-to-weight ratios (specific strength) and high rigidity-to-weight ratios (specific stiffness). Other thermosets include *cyanate esters*, which feature good moisture and heat resistance and better electrical properties; *polyetheramide* (PEA) from PEAR Industries for toughness and heat resistance; and, for aircraft interior parts, *phenolics*, which feature heat resistance and flame retardance. Thermoplastic matrices are not as commonly used but have potential advantages in moisture, heat, and impact resistance. These include polyamideimide (PAI), polyetheretherketone (PEEK), polyetherimide (PEI), and polyphenylene sulfide (PPS). Another advantage is that fiber direction can be oriented to suit applied load direction. Such composites are made by manual or automatic layout of thin (0.010 in. [0.254 mm]) prepreg plies or by filament winding, followed by curing in autoclaves or presses. Prepreg is a partially cured and somewhat tacky fiber-reinforced resin, which must be kept in refrigerated storage to keep from spoiling. Filament winding involves winding a tow of fibers or a series of tows (band) around a mandrel of the shape of the part to be produced. In “dry winding,” tows of prepreg are used. In “wet winding,” the tows or bands are first drawn through a resin bath.

C-Bar, or *composite rebar*, is a *PMC bar* developed by Marshall Industries Composites for reinforcing concrete. Intended to compete with epoxy-coated steel rebar, it consists of a protruded rod core of fiber-reinforced urethane-modified vinyl ester with a helically ribbed exterior of compression-molded, urethane-modified sheet molding compound to bond to concrete. The fibers, originally of E-glass, can also be aramid or graphite. The rebar is not conductive or corrodible, has a coefficient of thermal expansion closer to that of concrete than steel, and weighs about one-fourth as much as a comparable steel rod. Protruded fiber-reinforced epoxy plates are adhesive-bonded to form *glulams*—glued laminated beams—and used to locally reinforce wood glulams typically made of hemlock or Douglas fir plates.

Fabrication

Many processes are available for the fabrication of organic matrix composites. The first process is contact molding in order to orient the unidirectional layers at discrete angles to one another. Contact molding is a wet method, in which the reinforcement is impregnated with the resin at the time of molding. The simplest method is hand layup, whereby the materials are placed and formed in the mold by hand and the squeezing action expels any trapped air and compacts the part.

Molding may also be done by spraying, but these processes are relatively slow and labor costs are high, even though they can be automated. Many types of boats, as well as buckets for power-line servicing equipment, are made by this process.

Another process is vacuum-bag molding, where prepreps are laid in mold to form the desired shape. In this case, the pressure required to form the shape and achieve good bonding is obtained by covering the layup with a plastic bag and creating a vacuum. If additional heat and pressure are desired, the entire assembly is put into an autoclave. To prevent the resin from sticking to the vacuum bag and to facilitate

removal of excess resin, various materials are placed on top of the prepreg sheets. The molds can be made of metal, usually aluminum, but more often are made from the same resin (with reinforcement) as the material to be cured. This eliminates any problem with differential thermal expansion between the mold and the part.

In filament winding, the resin and fibers are combined at the time of curing. Axisymmetric parts, such as pipes and storage tanks, are produced on a rotating mandrel. The reinforcing filament, tape, or roving is wrapped continuously around the form. The reinforcements are impregnated by passing them through a polymer bath. However, the process can be modified by wrapping the mandrel with prepreg material. The products made by filament winding are very strong because of their highly reinforced structure. For example, filament winding can be used directly over solid-rocket-propellant forms.

Pultrusion is a process used to produce long shapes with constant profiles, such as rods or tubing, similar to extruded metal products. Individual fibers are often combined into a tow, yarns, or roving, which consists of a number of tows or yarns collected into a parallel bundle without twisting (or only slightly so). Filaments can also be arranged in a parallel array called a tape and held together by a binder. Yarns or tows are often processed further by weaving, braiding, and knitting or by forming them into a sheet-like mat consisting of randomly oriented chopped fibers or swirled continuous fibers held together by a binder.

Weaving to produce a fabric is a very effective means of introducing fibers into a composite. There are five commonly used patterns, which include box or plain, basket, crowfoot, long-shaft, and leno weave. Although weaving is usually thought of as a two-dimensional process, three-dimensional weaving is often employed.

Knitting is a process of interlooping chains of tow or yarn. Advantages of this process are that the tow or yarn is not crimped as happens in weaving, and higher mechanical properties are often observed in the reinforced product. Also, knitted fabrics are easy to handle and can be cut without falling apart.

In braiding, layers of helically wound yarn or tow are interlaced in a cylindrical shape, and interlocks can be produced at every intersection of fibers. During the process, a mandrel is fed through the center of a braiding machine at a uniform rate, and the yarn or tow from carriers is braided around the mandrel at a controlled angle. The machine operates like a maypole, the carriers working in pairs to accomplish the over-and-under sequencing. The braiding process is most effective for cylindrical geometries. It is used for missile heat shields, lightweight ducts, fluid-sealing components such as packings and sleeves, and tubes for insulation.

Metal–Matrix Composites (MMCs)

MMCs are usually made with alloys of aluminum, magnesium, or titanium, and the reinforcement is typically a ceramic in the form of particulates, platelets, whiskers, or fibers, although other systems may be used. MMCs are often classified as discontinuous or continuous depending on the geometry of the reinforcement. Particulates, platelets, and whiskers are in the discontinuous category, whereas the continuous category is reserved for fibers and wires. The type of reinforcement is important in the selection of an MMC because it determines virtually every aspect of the product, including mechanical properties, cost, and processing method. The primary methods for processing of discontinuous MMCs are powder metallurgy, liquid metal infiltration, squeeze or pressure casting, and conventional casting; however, most of these methods do not result in finished parts. Therefore, most discontinuously reinforced MMCs require secondary processing, which includes conventional wrought

metallurgy operations such as extrusion, forging, and rolling; standard and nonstandard machining operations; and joining techniques such as brazing and welding.

MMCs, like PMCs, were in use long before this term was coined. Examples include *cermets*, or ceramic-reinforced metals, such as *tungsten-carbide* particles in a cobalt matrix for cutting tools and *titanium-carbide* particles in steel for heat- and wear-resistant parts. MMCs may contain continuous or discontinuous fibers, particulates, whiskers or preforms as a reinforcing constituent. As a class, they are far more heat-resistant than PMCs. Among the MMCs that have been made are aluminum, copper, cobalt, lead, and magnesium reinforced with graphite. Boron has served as a reinforcement for aluminum, magnesium, and titanium; silicon carbide for aluminum, titanium, and tungsten; and alumina for aluminum. Compared with PMCs, applications so far have been limited, and these are largely limited to aluminum. Aluminum reinforced with continuous boron fibers is used for struts in the Space Shuttle, and aluminum reinforced with continuous graphite fibers is used for the Hubble telescope masts. *Fiber preforms* have been used to selectively reinforce cast aluminum products. Brake rotors made of 30% alumina in a 1%-magnesium aluminum alloy can operate at temperatures up to 1000°F (540°C) and 360 aluminum alloy with 30% silicon carbide has withstood 840°F (450°C). For semiconductor packaging, die-cast aluminum alloy with 70% silicon carbide provides low thermal expansion and high heat-dissipating thermal conductivity for superior reliability. *Titanium–matrix composites* are candidates for aircraft gas-turbine-engine parts. Pressure infiltration, mainly with either aluminum or magnesium alloys in porous ceramic, carbide, nitride, carbon, or graphite preforms, is used by Metal Matrix Cast Composites, Inc., to make MMCs. Pressureless infiltration is also used. For example, with the Primax Cast process, infiltrating a 30% by volume silicon carbide preform with *Lanxide 92-X-2050*, an aluminum, 10% silicon, 1% magnesium, 1% iron alloy results in an MMC with the density of 0.101 lb/in.³ (2796 kg/m³). *Aluminum alloys* reinforced with *alumina*, *boron carbide*, or *silicon carbide* particulates are commercially available as wrought and foundry products.

Ceramic–Matrix Composites (CMCs)

One type of CMC incorporates a continuous fiber, and another type a discontinuous reinforcement such as whiskers. Both approaches enhance fracture resistance, but the mechanism is substantially different. Continuous-fiber-reinforced ceramics resist catastrophic failure because, after the matrix fails, the fiber supports the load. When whiskers are used as reinforcements, the resistance to crack propagation is enhanced and hence the composite is less sensitive to flaws. However, once a crack begins to propagate, the failure will be catastrophic.

CMCs and IMCs are largely developmental. Both are promising for still greater heat resistance, although the inherent brittleness of the CMCs may limit their use in structural applications. Allied Signal makes CMCs using directed metal oxidation or chemical vapor infiltration techniques. Components include silicon carbide-particulate-reinforced *alumina* tubes and connecting sleeves for high-temperature air heaters and *silicon carbide–reinforced silicon carbide* panels for the vortex finder of a cyclone high-performance particle separator. The SiC/SiC panels were made by fabricating fiber preforms woven, braided, or wound to shape and infiltrating them with chemical vapors reacting at high temperature to form the silicon carbide matrix on and between the fibers. Matrix materials for discontinuously reinforced CMCs made by Triton Systems include *silicon carbide*, *hafnium carbide*, *tantalum carbide*, *boron nitride*,

or *silicon nitride*, and *refractory borides*. Continuous fiber CMCs include *carbon-reinforced silicon carbide*, *alumina-reinforced silicon carbide*, and *SiC/SiC*. *Silcomp*, from General Electric, comprises SiC fibers in an SiC and silicon matrix. It features low porosity, for oxidation and heat resistance, strength, and rigidity and may be suitable for gas-turbine-engine combustor liners and shrouds. A glass-fiber-reinforced CMC serves as armor in the U.S. Army's Crusader ground combat vehicle. Silicon nitride-coated fibers in a barium-strontium-aluminum-silicate glass that converts to a strong and tough glass ceramic on processing features low permittivity and electromagnetic absorption.

IMCs are seen as potential candidates for aircraft, aircraft-engine, and spacecraft components exposed to temperatures above 2000°F (1093°C). Promising matrix materials include *molybdenum disilicide* (MoSi_2), *nickel aluminides*, and *titanium aluminides*. Reinforcements include particles, whiskers, and continuous or discontinuous fibers of alumina or silicon carbide. MoSi_2 , which excels in corrosion and oxidation resistance, has a brittle-to-ductile transition temperature of about 1832°F (1000°C), but alloying with tungsten disilicide (WSi_2) improves toughness at lower temperatures. The nickel aluminide, Ni_3Al , with 0.5% boron and reinforced with alumina fibers, has a potential service temperature of 1500°F (816°C) or greater. For titanium aluminide, TiAl , reinforced with alumina, this temperature may approach 1900°F (1038°C), and for Ti_3Al with columbium, reinforced with silicon-carbide fibers, it is within the range of 1472°F–1562°F (800°C–850°C). An *SiC/SiC composite* from Allied Chemical is highly resistant to high concentrations of potassium and sodium both in chlorides and sulfides as well as to more complex compounds such as coal ash at temperatures up to 2100°F (1150°C).

Carbon–Carbon Composites (C–C)

Carbon–carbon composite is a specialized material made by reinforcing a carbon matrix with continuous carbon fiber. This type of composite has outstanding properties over a wide range of temperatures in both vacuum and inert atmospheres. It will even perform well at elevated temperatures in an oxidizing environment for short times. It has high strength, modulus, and toughness up to 2000°C; high thermal conductivity; and a low coefficient of thermal expansion. A material with such properties is excellent for rocket motor nozzles and exit cones, which require high-temperature strength as well as resistance to thermal shock. Carbon–carbon composites are also used for aircraft and other high-performance brake applications that take advantage of the fact that C–C composites have the highest energy capability of any known material. If a carbon–carbon composite is exposed to an O_2 -containing atmosphere above 600°C for an appreciable time, it oxidizes, and therefore it must be protected by coatings.

C–Cs are noted for their lightweight and good strength and low thermal expansion at temperatures greater than 3600°F (2000°C). A carbon-fiber-reinforced carbon piston developed at NASA Langley Research Center maintains high strength and stiffness at operating temperatures to over 2500°F (1371°C). C–Cs also have high thermal stability and nonoxidizing environments, are nonmelting and nonflammable, and possess low ablation and erosion rates. They are also tough and resistant to abrasion and corrosion, have a high thermal and electrical conductivity and high temperatures, and have excellent resistance to thermal shock. With *silicon carbide* as the oxygen-barrier coating, C–Cs service thermal-protection systems in the nose cone and wing leading edges of the Space Shuttle. Aircraft brake disks, 8–20 in. (200–500 mm) in diameter and 1–2 in. (25–50 mm) thick, are by far the largest-production use. Other applications include race-car brake and clutch components, heat sinks

for electronic circuit boards, solid- and liquid-propellant rocket-motor sections, aerospace-vehicle components, thermal insulation for spacecraft and vacuum or inert-gas furnaces, furnace trays and baskets, glass-production equipment, and high-temperature bolts, nuts, and rods.

Applications

The use of fiber-reinforced materials in engineering applications has grown rapidly. Selection of composites rather than monolithic materials is dictated by the choice of properties. The high values of specific stiffness and specific strength may be the determining factor, but in some applications wear resistance or strength retention at elevated temperatures is more important. A composite must be selected by more than one criterion, although one may dominate.

Components fabricated from advanced organic–matrix-fiber-reinforced composites are used extensively on commercial aircraft as well as for military transports, fighters, and bombers. The propulsion system, which includes engines and fuel, makes up a significant fraction of aircraft weight (frequently 50%) and must provide a good thrust-to-weight ratio and efficient fuel consumption. The primary means of improving engine efficiency are to take advantage of the high specific stiffness and strength of composites for weight reduction, especially in rotating components, where material density directly affects both stress levels and critical dynamic characteristics, such as natural frequency and flutter speed.

Composites consisting of resin matrices reinforced with discontinuous glass fibers and continuous glass-fiber mats are widely used in truck and automobile components bearing light loads, such as interior and exterior panels, pistons for diesel engines, drive shafts, rotors, brakes, leaf springs, wheels, and clutch plates.

The excellent electrical insulation, formability, and low cost of glass-fiber-reinforced plastics have led to their widespread use in electrical and electronic applications ranging from motors and generators to antennas and printed circuit boards.

Composites are also used for leisure and sporting products such as the frames of rackets, fishing rods, skis, golf club shafts, archery bows and arrows, sailboats, racing cars, and bicycles.

Advanced composites are used in a variety of other applications, including cutting tools for machining of superalloys and cast iron and laser mirrors for outer-space applications. They have made it possible to mimic the properties of human bone, leading to development of biocompatible prostheses for bone replacements and joint implants. In engineering, composites are used as replacements for fiber-reinforced cements and cables for suspension bridges. See also *carbon–carbon composites*, *ceramics–matrix composites*, *metal–matrix composites* and *resin–matrix composites*.

Composite Plate

An electrodeposit consisting of layers of at least two different compositions.

Composite Powder

A powder in which each particle consists of two or more different materials.

Composite Structure

A structural member (such as a panel, plate, pipe, or other shape) that is built up by bonding together two or more distinct components,

each of which may be made of a metal, alloy, nonmetal, or *composite material*. Examples of composite structures include: honeycomb panels, clad plate, electrical contacts, sleeve bearings, carbide-tipped drills or lathe tools, and weldments constructed of two or more different alloys.

Composition Metal

Also called *composition brass*, although it does not have the characteristics of a true brass. A general name for casting alloys, such as *copper alloy C83600*, that are in a midposition between the brasses and bronzes. The most widely used standard composition metal is *ounce metal*, containing 85% copper, 5% zinc, 5% tin, and 5% lead. It makes a good average bearing metal, and because it gives a dense casting that will withstand liquid pressures, it is also used for valves, pumps, and carburetor parts. It cast well, machines easily, and takes a good polish, so that is widely employed for mechanical castings. It has about the same coefficient of expansion as copper and can thus be used for pipe fitting. *ASTM alloy No. 2* is this metal, and it may also contain up to 1% nickel and small amounts of iron, either as intentional additions to increase strength or as impurities. This alloy has also been called *red casting brass*, *hydraulic bronze*, and *steam brass*, and it has also been used for forgings, producing parts with a tensile strength of 227 MPa and 25% elongation.

Compositional Depth Profile

In materials characterization, the atomic concentration measured as a function of the perpendicular distance from the surface.

Compound

(1) In chemistry, a substance of relatively fixed composition and properties, whose ultimate structural unit (molecule or repeat unit) is comprised of atoms of two or more elements. The number of atoms of each kind in this ultimate unit is determined by natural laws and is part of the identification of the compound. (2) In reinforced plastics and composites, the intimate admixture of a polymer with other ingredients, such as fillers, softeners, plasticizers, reinforcements, catalysts, pigments, or dyes. A thermoset compound usually contains all the ingredients necessary for the finished product, while a thermoplastic compound may require subsequent addition of pigments, blowing agents, and so forth.

Compound Compact

A powder metallurgy *compact* consisting of mixed metals, the particles of which are joined by pressing or sintering, or both, with each metal particle retaining substantially its original composition.

Compound Die

Any die designed to perform more than one operation on a part with one stroke of the press, such as blanking and piercing, in which all functions are performed simultaneously within the confines of the blank size being worked.

Compressibility

(1) The ability of a powder to be formed into a compact having well-defined contours and structural stability at a given temperature and pressure; and measure of the plasticity of powder particles.

(2) A density ratio determined under definite testing conditions. Also referred to as compactibility.

Compressibility Curve

A plot of the green density of a powder compact with increasing pressure.

Compressibility Test

In powder metallurgy, a test to determine the behavior of a powder under applied pressure. It indicates the degree of densification and cohesiveness of a compact as a function of the magnitude of the pressure.

Compression and Transfer Molded Plastics

Compression and transfer molding techniques are the most commonly used methods of molding thermosetting molding compounds as well as rubber parts. They may also be used for forming thermoplastic materials (e.g., compression molding of vinyl phonograph records), but usually other methods are more economical for molding thermoplastics.

The two processes are somewhat similar in terms of sizes and shapes produced. The major difference lies in the greater control of material flow permitted in transfer molding, allowing use of more delicate inserts and production of somewhat more complicated shapes.

Compression Molding

A technique of thermoset molding in which the plastic molding compound (generally preheated) is placed in the heated open mold cavity, the mold is closed under pressure (usually in a hydraulic press), causing the material to flow and completely fill the cavity, and then pressure is held until the material has cured.

The materials to be molded are generally softened by preheating in conventional ovens or, more frequently, in a dielectric preheating unit prior to placement in the mold.

Compression molding techniques are used most extensively for the manufacture of products made from thermosetting plastic materials and rubbers. These materials require the relatively high pressures and temperatures afforded by the compression molding process. Such materials include the phenolics, the melamines, the ureas, and the polyester resins. Under special circumstances, thermoplastics are compression-molded, but the injection molding process is usually more economical for the production of thermoplastic parts.

The process is ideal for the production of such items as thermosetting radio cabinets, television cabinets, trays, and other products that require resistance to heat. The size of the compression molded articles is generally limited only by the platen size and tonnage capacity of the presses used. Through the use of multicavity molds, small electrical components such as switch plates and terminal blocks may be produced economically. Compression molding is also used to produce extremely large parts such as fiberglass boat hulls and the complete fuselage for radio-controlled target aircraft.

Compression molding is not practical for many intricate products where complicated molds are required. Thermosetting materials are extremely stiff or viscous plastic masses during the mold-closing period. The internal pressures developed by these materials tend to distort or break delicate core pins and other

small mold components. The process also may be unsatisfactory for the production of extremely close tolerance articles, particularly where critical dimensions are influenced by the mold parting line. Flash thickness produced at the mold parting line tends to vary from cycle to cycle, thus changing the dimensions in the direction of the stroke of the press.

Molding pressures range from as low as 0.35 MPa for certain polyester compounds to as high as 2.3 kg/mm² for stiff high-impact phenolic materials. Process temperatures range from 121°C to 177°C depending upon the material used.

Thickness of the molded part influences production rates. A general rule of thumb allows a minute of mold close-time for each 3.2 mm of wall thickness. Standard dimensional tolerances are usually figured at ± 0.05 mm⁻¹, although closer tolerances can be held under special circumstances. Where phenolic and urea materials are to be molded, hardened steel is used for the mold construction. Such molds are usually carburized and hardened to about 50 Rockwell C. For use with polyester materials, where pressure requirements are not high, prehardened steel at about 38 Rockwell C is usually satisfactory.

Transfer Molding

Transfer molding is best described as a closed-mold technique wherein the material is injected or transferred into a closed mold through a gate or runner system. Essentially, transfer molding is a one-shot injection molding technique. The process is particularly adaptable again to thermosetting materials, since these materials retain their plastic condition after preheating for only a short length of time.

Generally, the comments made regarding compression molding apply to this process as well. The distinct advantage in the transfer molding process lies in the fact that the mold is completely closed and under clamping pressure before the material is injected into the mold cavity. This results in little or no flash and accurate control of dimensions.

A preweighted material charge is plasticized generally in a dielectric preheating unit. The charge is then placed in a pot that is usually positioned above the closed mold. A ram enters the pot and forces the material through an orifice into the closed mold. The transfer plunger and mold are kept under pressure for a predetermined time to allow the chemical/heat hardening process to proceed. When the mold is opened, the small amount of material remaining in the transfer pot and that which has filled the orifice is removed as a cull and discarded.

Transfer molding generally operates at faster cycles than compression molding. Because of the highly plastic condition of the material, complex part designs involving cores, undercuts, and moving die parts are best adapted to this process. Molded-in inserts can be held in position more easily in the transfer molding operation. Since the mold is closed during the entire molding operation, control of dimensions is more satisfactory.

With a properly designed mold, transfer molded articles require fewer finishing operations with a resultant lower net cost.

The process results in higher material costs due to the loss of material in the transfer pot and runner system. High-impact phenolic materials have generally lower physical properties when transfer molded compared with those obtained by compression molding.

Transfer molding techniques are used in the manufacture of a wide range of product shapes and sizes. Small, complex electrical components with molded-in terminals are made by this process. Radio and television cabinets weighing up to 1.7 kg have been transfer molded from phenolic materials.

Compression Crack

See *compacting crack*.

Compression Modulus

See *bulk modulus of elasticity*.

Compression Ratio (Plastics)

In an extruder screw, the ratio of the volume available in the first flight at the hopper to the volume at the last flight, at the end of the screw.

Compression Ratio (Powder Metallurgy)

The ratio of the volume of the loose powder to the volume of the compact made from it.

Compression Set

In seals, the difference between the thickness of a gasket of static seal before the seal is compressed and after it is released from compression. Compression set is normally expressed as a percentage of the total compression.

Compression Test

A method for assessing the ability of a material to withstand compressive loads. Analyses of structural behavior or metal-forming require knowledge of compression stress-strain properties. Failure modes include cracking, buckling, and general collapse.

Compressive

Pertaining to forces on a body or part of a body that tend to crush, or compress, the body.

Compressive Modulus

The ratio of compressive stress to compressive strain below the proportional limit. Theoretically equal to Young's modulus determined from tensile experiments.

Compressive Strength

The maximum compressive stress that a material is capable of developing, based on original area of cross section. If a material fails in compression by a shattering fracture, the compressive strength has a very definite value. If a material does not fail in compression by a shattering fracture, the value obtained for compressive strength is an arbitrary value depending upon the degree of distortion that is regarded as indicating complete failure of the material.

Compressive Stress

A stress that causes an elastic body to deform (shorten) in the direction of the applied load. Contrast with *tensile stress*.

C

Compressometer

Instrument for measuring change in length over a given gauge length caused by application or removal of a force. Commonly used in compression testing of metal specimens.

Compton Scattering

In materials characterization, the elastic scattering of photons by electrons. Contrast with *Rayleigh scattering*.

Computed Tomography (CT)

The collection of transmission data through an object and the subsequent reconstruction of an image corresponding to a cross section through this object. Also known as computerized axial tomography, computer-assisted tomography, CAT scanning, or industrial computed tomography.

Computer Aided (Assisted) Design (CAD)

Design techniques employing computer-based mathematical and graphics programs to assist in matters such as stress determination, computer layout, and product appearance.

Computer Aided (Assisted) Manufacture (Machining) (CAM)

Processes employing computers to assist in matters such as monitoring of product dimensions, rectification of deviations, etc.

ConCast

Continuously cast material or the continuous casting process.

Concave Grating

In materials characterization, a diffraction grating on a concave mirror surface. See also diffraction grating and plane grating.

Concave Root

An indentation along the line of the weld root. Same as root concavity.

Concave Root Surface

A root surface which is concave.

Concave Weld

Any weld including butt and fillet in which the exposed weld surface falls below a line joining the points where the weld metal meets the parent metal.

Concavity

The maximum distance from the face of a concave fillet weld perpendicular to a line joining the toes.

Concentration

(1) The mass of a substance contained in a unit volume of sample, for example, grams per liter. (2) A process for enrichment of an ore in valuable mineral content by separation and removal of waste material, or *gangue*. (3) The quantity of one substance contained in another, usually as a percentage.

Concentration Cell

An *electrolytic cell*, the *electromotive force* of which is caused by a difference in concentration of some component in the electrolyte. This difference leads to the formation of discrete *cathode* and *anode* regions.

Concentration Gradient

A variation, from point-to-point, and the proportion of two or more elements. The gradient may be a sharp step, as at the boundary between two phases, or it may be a shallow slope as in coring.

Concentration Polarization

That portion of the *polarization* of a cell produced by concentration changes resulting from passage of current through the electrolyte.

Conchoidal Markings

Concentric marks on the surface of a fatigue fracture. They are visible to the unaided eye and marked the crack front at irregularities in the load cycling such as interruptions in cycling or an abnormal load. Also termed *beach marks*, *shell marks* or *arrest marks*. Compare with *striations*.

Concrete

(1) A composite material that consists essentially of a binding medium within which are embedded particles or fragments of aggregates (maximum aggregate size >5 mm, or 0.2 in.). In hydraulic-cement concrete, the binder is formed from a mixture of hydraulic cement and water. (2) A homogenous mixture of portland cement, aggregates, and water and which may contain admixtures. See also *cement*.

Concrete is a construction material composed of portland cement and water combined with sand, gravel, crushed stone, or other inert material such as expanded slag or vermiculite. The cement and water form a paste that hardens by chemical reaction into a strong stone-like mass. The inert materials are called aggregates, and for economy no more cement paste is used than is necessary to coat all the aggregate surfaces and fill all the voids. The concrete paste is plastic and easily molded into any form or troweled to produce a smooth surface. Hardening begins immediately, but precautions are taken, usually by covering, to avoid rapid loss of moisture because the presence of water is necessary to continue the chemical reaction and increase the strength. Too much water, however, produces a concrete that is more porous and weaker. The quality of the paste formed by the cement and water largely determines the character of the concrete.

Proportioning of the ingredients of concrete is referred to as designing the mixture, and for most structural work the concrete is designed to give compressive strengths of 16–34 MPa. A rich mixture for columns may be in the proportion of 1 volume of cement to

1 of sand and 3 of stone, whereas a lean mixture for foundations may be in the proportion of 1:3:6. Concrete may be produced as a dense mass that is practically artificial rock, and chemicals may be added to make it waterproof, or it can be made porous and highly permeable for such use as filter beds. An air-entraining chemical may be added to produce minute bubbles for porosity or light weight. Normally, the full hardening period of concrete is at least 7 days. The gradual increase in strength is due to the hydration of the tricalcium aluminates and silicates. Sand used in concrete was originally specified as roughly angular, but rounded grains are now preferred. The stone is usually sharply broken. The weight of concrete varies with the type and amount of rock and sand. A concrete with trap rock may weigh 2483 kg/m³. Concrete is stronger in compression than in tension, and steel bars or mesh are embedded in structural members to increase the tensile and flexural strengths. In addition to the structural uses, concrete is widely used in precast units such as block, tile, sewer and water pipe, and ornamental products.

Concretes are similar in composition to mortars, which are used to bond unit masonry. Mortars, however, are normally made with sand as the sole aggregate, whereas concretes contain much larger aggregates and thus usually have greater strength. As a result, concretes have a much wider range of structural applications, including pavements, footings, pipes, unit masonry, floor slabs, beams, columns, walls, dams, and tanks.

Classification

Concretes may be classified as flexible or rigid. These characteristics are determined mainly by the cementitious materials used to bond the aggregates. Flexible concretes tend to deform plastically under heavy loads or when heated. Rigid concretes are considerably stronger in compression than in tension and tend to be brittle. To overcome this deficiency, strong reinforcement may be incorporated in the concrete, or prestress may be applied to keep the concrete under compression.

Flexible Concretes

Usually, bituminous or asphaltic concretes are used when a flexible concrete is desired. The main use of such concretes is for pavements.

The aggregates generally used are sand, gravel or crushed stone, and mineral dust; the binder is asphalt cement, an asphalt specially refined for the purpose. A semisolid at normal temperatures, the asphalt cement may be heated until liquefied for bonding the aggregates. Ingredients usually are mixed mechanically in a pug mill, which has pairs of blades revolving in opposite directions. While the mix is still hot and plastic, it can be spread to a specified thickness and shaped with a paving machine and compacted with a roller or by tamping to a desired density. When the mix cools, it hardens sufficiently to withstand heavy loads.

Sulfur, rubber, or hydrated lime may be added to an asphalt-concrete mix to improve the performance of the product.

Rigid Concretes

Ordinary rigid concretes are made with portland cement, sand, and stone, or crushed gravel. The mixes incorporate water to hydrate the cement to bond the aggregates into a solid mass. Admixtures may be added to the mix to impart specific properties to it or to the hardened concrete.

Other types of rigid concretes include nailable concretes; insulating concretes; heavyweight concretes; lightweight concretes; fiber-reinforced concretes, in which short steel or glass fibers are embedded for resistance to tensile stresses; polymer and pozzolan

concretes, which exhibit improvement in several properties; and silica-fume concretes, which possess high strength. Air-entrained concrete formulations, in which tiny air bubbles have been incorporated, may be considered variations of ordinary concrete.

Stress and Reinforcement

Because ordinary concrete is much weaker in tension than in compression, it is usually reinforced or prestressed with a much stronger material, such as steel, to resist tension. Use of plain, or unreinforced, concrete is restricted to structures in which tensile stresses will be small, such as massive dams, heavy foundations, and unit-masonry walls. For reinforcement of other types of structures, steel bars or structural steel shapes may be incorporated in the concrete.

Cementitious Materials

These are for general-purpose cements, cements modified to achieve low heat of hydration and to produce a concrete resistant to sulfate attack, high-early-strength cement, and air-entraining cement.

Several other types of cement are sometimes used instead of portland cement for specific applications—for example, hydraulic cements, which can set and harden underwater. Included in this category, in addition to, are aluminous, natural, and white portland cements, and blends, such as portland blast-furnace slag, portland-pozzolan, and slag cements.

Aggregates for Ordinary Concrete

Aggregates should be inert, dimensionally stable particles, preferably hard, tough, and round or cubical. They should be free of clay, silt, organic matter, and salts.

Polymer Concretes

Polymers are used in several ways to improve concrete properties; they are impregnated in hardened concrete, are incorporated in a mix, or replace portland cement.

Impregnation is sometimes used for concrete road surfaces. It can more than double compressive strength and elastic modulus, decrease creep, and improve resistance to freezing and thawing.

Monomers and polymers added as admixtures are used for restoring and resurfacing deteriorated roads. The concrete hardens more rapidly than ordinary concrete, enabling faster return of roads to service.

Polymer concretes in which a polymer replaces portland cement possess strength and other properties similar to those of impregnated concrete. After curing for a relatively short time, for example, overnight at room temperatures, polymer concretes are ready for use; in comparison, ordinary concrete may have to cure for a week or more before exposure to service loads.

Casting

There are various methods employed for casting ordinary concrete. For very small projects, sacks of prepared mixes may be purchased and mixed on the site with water, usually in a drum-type, portable, mechanical mixer. For larger projects, mix ingredients are weighed separately and deposited in a stationary batch mixer, a truck mixer, or a continuous mixer. Concrete mixture agitated in a truck is called ready-mixed concrete. Paving mixers are self-propelled, track-mounted machines that move at about 0.45 m/s while mixing.

At the site, concrete may be conveyed to the forms in wheelbarrows, carts, trucks, chutes, conveyor belts, buckets, or pipelines. Where chutes or belts are used, the flow of material is maintained as continuous as possible. On large projects, concrete may be delivered to the formwork in dump buckets by cableways or by cranes. In many instances, direct pumping through pipelines is used to convey concrete from the mixer or hopper to the point of placement.

Concurrent Heating

The application of supplemental heat to a structure during a welding or cutting operation.

Condensate

Same as condensation except that the term usually implies bulk liquid such as would be produced in a condenser.

Condensation

(1) A chemical reaction in which two or more molecules combine, with the resulting separation of water or some other simple substance; the process is called polycondensation if a polymer is formed. (2) Liquid precipitated from the gaseous phase. The term may imply films were small volumes of liquid. See also *polymerization*.

Condensation Polymerization

In plastics technology, a stepwise chemical reaction in which two or more molecules combine, often but not necessarily accompanied by the separation of water or some other simple substance. If a polymer is formed, the process is called polycondensation. See also *polymerization*.

Condensation Ratio

A resin formed by polycondensation, for example, the alkyd, phenylaldehyde, and urea-formaldehyde resins.

Condenser

(1) A heat exchanger, in which a gas, often steam, is cooled causing it to revert to the liquid state. In a tube condenser cooling water is circulated through tubes to condense the steam exhausting from a steam turbine or other cycle. In a jet condenser the cooling water is injected into the exhaust steam; this requires high-quality cooling water. (2) An electrical capacitor. (3) A term applied to lenses or mirrors designed to collect, control, and concentrate radiation in an illumination system, such as an optical or scanning electron microscope.

Condenser Aperture

In electron microscopy, an opening in the condenser lens controlling the number of electrons entering the lens and the angular aperture of the illuminating beam.

Condenser Foil

Metal foil, usually aluminum or tin base, used for electrical capacitors, i.e., condensers. The foil may be varnished or, in the

case of aluminum anodized, to provide an insulating surface to avoid the need for a nonconducting interleaf when rolled to form the capacitor.

Condenser Lens

See *condenser*.

Conditioning

Subjecting a material to a prescribed environmental and/or stress history before testing.

Conditioning Heat Treatment

A preliminary heat treatment used to prepare a material for a desired reaction to a subsequent heat treatment. For the term to be meaningful, the exact heat treatment must be specified.

Conditioning Time

See *joint-conditioning time*, *curing time*, and *setting time*.

Conductance (Electrical)

A measure of the ability of any material to conduct an electrical charge. Conductance is the ratio of the current flow to the potential difference. The reciprocal of electrical resistance.

Conductance (Thermal)

The time rate of heat flow through a unit area of a body, induced by a unit temperature difference between the body surfaces.

Conduction Band/Electrons

See *Band Theory*.

Conductive (Electrical) Polymers and Elastomers

These are polymers made electrically conductive by the addition of carbon black, nickel, silver, or other metals. Volume resistivities of plastics and rubbers, which normally are in excess of $10^8 \Omega/\text{cm}$, can be lowered to between 10^{-1} and $10^6 \Omega/\text{cm}$ by addition of conductive materials. Carbon black is the most widely used filler. The relationship of carbon black loading and volume resistivity is not proportioned. Up to a 25% loading, conductivity significantly increases, but it falls off sharply thereafter. Generally, the addition of carbon black lowers the mechanical properties of the polymer. However, the use of carbon fibers to enhance conductivity improves mechanical properties.

Polyethylene and polyvinyl chloride resins loaded with carbon black are perhaps the most widely used conductive plastics. Plastics often made conductive by adding up to 30% carbon fiber are polysulfone, polyester, polyphenylene sulfide, nylon 6/6, ethylene tetrachloroethylene, and vinylidene fluoride-polytetrachloroethylene.

Although silicone is the most widely used base polymer for conductive rubber, other rubbers frequently used in compounding conductive elastomers include SBR, EPDM, TPR, and neoprene.

Another type of electrically conductive polymer includes materials that are doped with either electron acceptors, such as alkali metal ions and iodine, or electron donors, such as arsenic trifluoride. Also referred to as organic conductors, their conductivity is about one-hundredth that of copper. The most widely used are polyacetylene, polyparaphenylene, and polyparaphenylene sulfide.

Conductivity (Electrical)

The reciprocal of volume resistivity. The electrical or thermal conductance of a unit cube of any material (conductivity per unit volume).

Conductivity (Thermal)

The time rate of heat flow through unit thickness of an infinite slab of a homogeneous material in a direction perpendicular to the surface, induced by unit temperature difference. Recommended SI units: W/m K. See also IACS.

Conductors

This term is usually applied to materials (wire, cable, or other body), generally metals, used to conduct electric current, although heat conductors and sound conductors have important uses. Good conductors of electricity tend to be good conductors of heat, as well. Silver is the best conductor of electricity, but copper is the most commonly used. The conductivity of pure copper is 97.6% that of silver. The electric conductivity of metals is often expressed as a percentage of the electric conductivity of copper, which is arbitrarily set at 100%. Tough-pitch copper is the standard conductivity metal, and it is designated as the International Annealed Copper Standard (IACS).

Because of the low conductivity of zinc, the brasses have low current-carrying capacity, but are widely used for electric connections and parts because of their workability and strength. The electric conductivity of aluminum is only 63% that of copper, but it is higher than that of most brasses. Copper wire for electric conductors in high-temperature environments has a plating of heat-resistant metal. Aluminum wire with a steel core is used for power transmission because of the long spans possible. Steel has a conductivity only about 12% that of copper, but the current in a wire tends to travel near the surface, and the small steel core does not reduce greatly the current-carrying capacity. Aluminum is now widely used to replace brass in switches and other parts. Aluminum wire for electric equipment is usually commercially pure aluminum with small amounts of alloying elements, such as magnesium, which give strength without appreciably reducing the conductivity. Plastics, glass, and other non-conductors are given conductive capacity with coatings of transparent lacquer containing metal powder, but conductive glass usually is made by spraying on at high temperature an extremely thin invisible coating of SnO. Coated glass panels are available with various degrees of resistivity.

Cone

The conical part of an oxyfuel gas flame next to the orifice of the tip.

Cone Angle

The angle that the cutter axis makes with the direction along which the blades are moved for adjustment, as in adjustable-blade reamers where the base of the blade slides on a conical surface.

Cone Resistance Value (CVR)

A measure of the yield stress of a grease, obtained by static indentation with a cone. The equilibrium depth of penetration is measured, not the penetration in a given time, which is the penetration value. See also *penetration* (of a grease).

Confidence Interval

That range of values, calculated from estimates of the mean and standard deviation, which is expected to include the population mean with a stated level of confidence. Confidence intervals in the same context also can be calculated for standard deviations, lines, slopes, and points.

Configurations

In plastics technology, related chemical structures produced by the cleavage and reforming of covalent bonds.

Confirmations

Different shapes of polymer molecules resulting from rotation about single covalent bonds in the polymer chain.

Conformability

In tribology, that quality of a plain bearing material that allows it to adjust itself to shaft deflections and minor misalignments by deformation or by wearing away of bearing material without producing operating difficulties.

Conformal Surfaces

Surfaces whose centers of curvature are on the same side of the interface. In wear testing, it refers to the case where the curvature of both specimens matches such that the nominal contact area during the testing remains approximately constant. Contrast with *counterformal surfaces*.

Congruent Melting

An isothermal or isobaric melting in which both the solid and liquid phases have the same composition throughout the transformation.

Congruent Transformation

An isothermal or isobaric phase change in metals in which both of the phases concerned have the same composition throughout the process.

Conjugate Phases

In microstructural analysis, those states of matter of unique composition that coexist at equilibrium at a single point in temperature and pressure. For example, the two coexisting phases of a two-phase equilibrium.

Conjugate Planes

Two planes of an optical system such that one is the image of the other.

C

Connected Porosity

The volume fraction of all pores, voids, and channels within a solid mass that are interconnected with each other and communicate with the external surface, and thus are measurable by gas or liquid penetration. Contrast with *closed porosity*.

Consistency

(1) In adhesives, that property of a liquid adhesive by virtue of which it tends to resist deformation. Consistency is not a fundamental property but is composed of viscosity, plasticity, and other phenomena. See also *viscosity* and *viscosity coefficient*. (2) An imprecise measure of the degree to which a grease resists deformation under the application of a force.

Consolidation

In metal–matrix or thermoplastic composites, a processing step in which fiber and matrix are compressed by one of several methods to reduce voids and achieve desired density.

Constant Life Fatigue Diagram

In failure analysis, a plot (usually on rectangular coordinates) of a family of curves, each of which is for a single fatigue life (number of cycles), relating alternating stress, maximum stress, minimum stress, and mean stress. The constant life fatigue diagram is generally derived from a family of *S–N* curves, each of which represents a different stress ratio for a 50% probability of survival. See also *nominal stress*, *maximum stress*, *minimum stress*, *S–N curve*, *fatigue life*, and *stress ratio*.

Constantan

An alloy of 60% copper with 40% nickel having high electrical resistivity, about $48 \mu\Omega \text{ cm}$, a low temperature coefficient of resistivity up to about 450°C and good corrosion resistance. It is used for various electrical purposes, such as resistors and thermocouples. See *resistance alloys*.

Constituent

(1) One of the ingredients that make up the chemical system. (2) A phase or a combination of phases that occurs in a characteristic configuration in an alloy microstructure. (3) In composites, the principal constituents are the fibers in the matrix.

Constraint

(1) Any restriction that limits the transverse contraction normally associated with a longitudinal tension, and that hence causes a secondary tension in the transverse direction; usually used in connection with welding. Contrast with *restraint*. (2) (of deformation) Localized restriction of deformation resulting from the Poisson effect, i.e., as the material is extended along one axis it has to contract across the transverse axes. At notches and other stress concentrations the material at the highly stressed notch tip is constrained from contraction in the transverse axes by the surrounding large volume of lower stress material. This gives rise to complex triaxial stresses at the notch tip. The effect is usually confined to small volumes of material while

stresses are in the elastic range but large volumes may be involved if plastic deformation has occurred.

Constricted Arc (Plasma Arc Welding and Cutting)

A plasma arc column that is shaped by a constricting nozzle orifice. See also *plasma arc welding*.

Constricting Nozzle (Plasma Arc Welding and Cutting)

A water-cooled copper nozzle surrounding the electrode and containing the constricting orifice. See also *cutting torch (plasma arc)*.

Constricting Orifice (Plasma Arc Welding and Cutting)

The hole in the constricting nozzle through which the arc passes. See also *multi-port nozzle*.

Constriction Resistance

In electrical contact theory, the resistance that arises from the constriction of current flow lines in order to pass through small areas of contact (a-spots) at the interface of two connecting bodies. See also *a-spot*, *contact resistance*, and *film resistance*.

Consumable Electrode

A general term for any arc welding electrode made chiefly of filler metal. Use of specific names such as *covered electrode*, *bare electrode*, *flux-cored electrode*, and *lightly coated electrode* is preferred.

Consumable Guide Electroslag Welding

In electroslag welding process variation in which filler metal is supplied by an electrode and its guiding member. See also *electroslag welding*.

Consumable Insert (of Weld)

A preplaced filler having specific dimensions that is located in the root of a joint to be made from one side. It is intended to be fully fused to become an integral part of the joint and is not normally machined following welding. Same as *fusible insert*.

Consumable-Electrode Remelting

A process for refining metals in which an electric current passes between electrode made of the metal to be refined in an ingot of the refined metal, which is contained in a water-cooled mold. As a result of the passage of electric current, droplets of molten metal form on the electrode and fall to the ingot. The refining action occurs from contact with the atmosphere, vacuum, or slag through which the drop falls. See also *electro slag remelting* and *vacuum arc remelting*.

Contact Adhesive

An adhesive that is apparently dry to the touch and that will adhere to itself simultaneously upon contact. An adhesive that, when applied to both adherends and allowed to dry, develops a bond when the adherends are brought together without sustained pressure.

Contact Angle

(1) See *roll angle*. (2) The angle formed at the junction between a solid and a liquid. If the liquid “wets” the solid as with water on clean glass the angle is acute, if it does not wet as with water droplets on a wax car body the angle is obtuse. (3) (in a bearing). See *angle of contact*.

Contact Area

The common area between a conductor and a connector across which the flow of electricity takes place.

Contact Bond Adhesive

Synonym for *contact adhesive*.

Contact Corrosion

(1) Corrosion in the vicinity of the point of contact between dissimilar metals in electrolyte. (2) A term primarily used in Europe to describe galvanic corrosion between dissimilar metals.

Contact Electrode (for Welding)

An electrode, the coating of which during the welding operation maintains a cup profile projecting slightly beyond the tip of the metal electrode. The edge of the cup is rested against the component being welded to maintain a fixed arc length.

Contact Fatigue

Cracking and subsequent pitting of a surface subjected to alternating Hertzian stresses such as those produced under rolling contact or combined rolling and sliding. The phenomenon of contact fatigue is encountered most often in rolling-element bearings or in gears, where the surface stresses are high due to the concentrated loads and are repeated many times during normal operation.

Contact Infiltration

In powder metallurgy, the process of infiltration whereby the initially solid infiltrant is placed in direct contact with the compact and the pores are filled with the liquid phase by capillary force after the infiltrant has become molten. See also *infiltrant* and *infiltration*.

Contact Material

A metal, composite, or alloy made by the melt-cast method or manufactured by powder metallurgy that is used in devices that make and break electrical circuits or welding electrodes. A majority of contact applications in the electrical industry utilize silver-type contacts, which include the pure metal, alloys, and powder metal combinations. Silver, which has the highest electrical and thermal conductivity of all metals, is also used as a plated, brazed, or mechanically bonded overlay on other contact materials—notably, copper and copper-base materials. Other types of contacts used include the platinum group metals, tungsten, molybdenum, copper, copper alloys, and mercury. See also *electrode (welding)*.

Contact Molding

A process for molding reinforced plastics in which reinforcement and resin are placed in a mold. Cure is either at room temperature using a catalyst-promoter system or by heating in an oven, without additional pressure. Also referred to as hand lay-up.

Contact Plating

(1) The plated-on material applied to the basic metal of an electrical contact to provide for required contact resistance and/or specified wear resistance characteristics. (2) A metal plating process wherein the plating current is provided by galvanic action between the work metal and a second metal, without the use of an external source of current.

Contact Potential

In corrosion technology, the potential difference at the junction of two dissimilar substances.

Contact Pressure Resins

Liquid resins that thicken or polymerize upon heating, and, when used for bonding laminates, require little or no pressure.

Contact Resistance

(1) It reflects aspects such as contact area, roughness, interfacial pressure and contamination. (2) The electrical resistance of metallic surfaces at their interface in the *contact area* under specified conditions. (3) The electrical resistance between two contacting bodies, which is the sum of the *constriction resistance* and the *film resistance*.

Contact Scanning

In ultrasonic inspection, a planned systematic movement of the beam relative to the object being inspected, the search unit being in contact with and coupled to this object by a thin film of coupling material.

Contact Stress

Stress that results near the surfaces of two contacting solid bodies when they are placed against one another under a nonzero normal force. This term is not sufficiently precise because it does not indicate the type of stress, although common usage usually implies elastic or Hertz stress.

Contact Stress (Glass)

The tensile stress component imposed at a glass surface immediately surrounding the contact area between the glass surface and an object generating a locally applied force.

Contact Tube

A device which transfers current to a continuous welding electrode.

Contact Weld

(1) The point of attachment of a contact to its support when accomplished by resistance welding. (2) A contacting failure due to the fusing of contacting surfaces under load conditions to the point that the contacts failed to separate when expected.

Contacting Ring Seal

A type of circumferential seal that utilizes a ring-spring loaded radially against the shaft. The ring is either gapped or segmented, in order to have radial flexibility. The seal has overlapping joints for blocking leakage at the gaps. An axial spring load seats the ring against the wall of its containing cartridge.

Container

The chamber into which an ingot or billet is inserted prior to extrusion. The container for backward extrusion of cups or cans is sometimes called a die.

Contaminant

An impurity or foreign substance present in a material or environment that affects one or more properties of the material.

Context Root Surface

A root surface which is convex.

Continuous Furnace (Glass)

A glass furnace in which the level of glass remains substantially constant because the feeding of batch continuously replaces the glass withdrawn.

Continuity Bond

In corrosion protection, a metallic connection that provides electrical continuity between metal structures.

Continuous Casting

Any system using a mold open at both ends such that solid metal is steadily drawn out of the bottom while molten metal continues to enter the top. The mold can be in various forms including a simple die or rolls and is usually water cooled. Often, equipment beyond the mold cuts the ingot, bar, tube, etc., into lengths allowing the process to continue virtually indefinitely. If the process is occasionally interrupted to allow removal of the ingot the process may be termed Semi-continuous casting. Used chiefly to produce semi-finished mill products such as billets, blooms, ingots, slabs, strip, and tubes. See also *strand casting*.

Continuous Compaction

In powder metallurgy, the production of relatively long compacts having a uniform cross-section, such as sheet, rod, tube, etc. By direct extrusion or rolling of loose powder.

Continuous Cooling Transformation (CCT) Diagram

Set of curves drawn using logarithmic time and linear temperature as coordinates, which define, for each cooling curve of an alloy, the beginning and end of the transformation of the initial phase. See *Isothermal Transformation Diagram*.

Continuous Covered Electrode

Welding electrode filler wire, supplied as coils, comprising a central main filler wire carrying an external coating and helical wire(s) which reinforced the coating and act as current pickup.

Continuous Filament Yarn

Yarn formed by twisting two or more continuous filaments into a single, continuous strand.

Continuous Furnace

A furnace which operates continually with materials being charged at one end and discharged at the other. A variation is the Rotary Hearth where the charge and discharge points are a short distance apart around the radius.

Continuous Furnace (Powder Metallurgy)

A furnace used for the uninterrupted sintering of compacts.

Continuous Mill

A rolling mill consisting of a number of strands of synchronized rolls (in tandem) in which metal undergoes successive reductions as it passes through the various strands.

Continuous Phase

In an alloy or portion of an alloy containing more than one phase, the phase that forms the matrix in which the other phase or phases are dispersed.

Continuous Precipitation

Precipitation from a supersaturated solid solution in which the precipitate particles grow by long-range diffusion without recrystallization of the matrix. Continuous precipitates grow from nuclei distributed more or less uniformly throughout the matrix. They usually are randomly oriented, but may form a *Widmanstätten structure*. Also called general precipitation. Should be compared with *discontinuous precipitation* and *localized precipitation*.

Continuous Sequence

A longitudinal welding sequence in which each pass is made continuously from one end of the joint to the other. See also *backstep sequence* and *longitudinal sequence*.

Continuous Sintering

In powder metallurgy, presintering or sintering in such a manner that the objects are advanced through a furnace at a fixed rate by manual or mechanical means; sometimes called stoking.

Continuous Spectrum (X-Rays)

In materials characterization, the polychromatic radiation emitted by the target of an x-ray tube. It contains all wavelengths above a certain minimum value, known as the short wavelength limit.

Continuous Weld

A weld extending continuously from one end of a joint to the other or, where the joint is essentially circular, completely around the joint. Contrast with *intermittent weld*.

Continuous-Type Furnace

A furnace used for heat treating materials that progress continuously through the furnace, entering one door and being discharged from another. See also *belt furnace*, *direct-fired tunnel-type furnace*, *rotary-retort furnace*, and *shaker-hearth furnace*.

Continuum

In materials characterization, the noncharacteristic rays emitted upon irradiation of a specimen and caused by deceleration of the incident electrons by interaction with the electrons and nuclei of the specimen. Also termed *bremsstrahlung* and *white radiation*.

Contour Forming

See *roll forming*, *stretch forming*, *tangent bending*, and *wiper forming*.

Contour Machining

Machining of irregular surfaces, such as those generated in tracer turning, tracer boring, and tracer milling.

Contour Milling

Milling of irregular surfaces. See also *tracer milling*.

Contraction

The volume change that occurs in metals and alloys upon solidification and cooling to room temperature. See *shrinkage*.

Contrast Enhancement (Electron Optics)

In electron microscopy, an improvement of electron image contrast by the use of an objective aperture diaphragm, shadow casting, or other means. See also *shadowing*.

Contrast Filter

In metallography, a color filter, usually with strong absorption, that uses the special absorption bands of the object to control the contrast of the image by exaggerating or diminishing the brightness difference between differently colored areas.

Contrast Perception

In metallography, the ability to differentiate various components of the object structure by various intensity levels in the image.

Controlled Atmosphere

(1) A specified inert gas or mixture of gases at a predetermined temperature in which selected processes take place. (2) As applied to sintering, to prevent oxidation and destruction of the powder compacts.

Controlled Atmosphere Chamber

An inert gas-filled enclosure or cabinet in which plasma spraying or welding can be performed to minimize (or prevent) oxidation of the coating or substrate. The enclosure is usually fitted with viewing ports, glove ports to permit manipulations, and a small separate airlock for introducing or removing components without loss of atmosphere.

Controlled Cooling

Any cooling at a prescribed rate but it is usually implicit that the rate is slower than would occur naturally, as opposed to quenching. It is imposed after heat treatment, welding or hot working for various reasons including avoiding hardening, minimizing residual stresses or allowing dissolved hydrogen to escape.

Controlled Etching

Electrolytic etching with selection of suitable etchant and voltage resulting in a balance between current and dissolved metal ions.

Controlled Rolling

A hot-rolling process in which the temperature of the steel is closely controlled, particularly during the final rolling passes, to produce a fine-grain microstructure.

Controlled Thermal Severity Test

A test of the weldability of steels, in particular the relationship between cooling rate and susceptibility to cracking. For the test, a 3 in.² steel plate is bolted to a much larger and thicker steel plate and substantial fillet welds deposited along two opposite sides. Two test welds are then deposited, in sequence, on the remaining sides. The concept is that when the first test weld is deposited the cooling rate is controlled by the conduction of heat through the two assembly welds while the cooling rate for the second test weld is controlled by conduction through the previous three welds. The severity of the test is defined in terms of Thermal Severity Number, TSN, which is the number of conduction paths multiplied by the plate thickness in units of 0.25 in. For example, with quarter inch plate the TSNs of the test welds would be 2 and 3, and with half inch plate they would be 4 and 6.

Controlled-Potential Coulometry

Measurement of the number of coulombs required for an electrochemical reaction occurring under conditions where the working electrode potential is precisely controlled.

Controlled-Pressure Cycle

A forming cycle during which the hydraulic pressure in the forming cavity is controlled by an adjustable cam that is coordinated with the punch travel.

C

Convection

The motion resulting in a fluid from the differences in density and the action of gravity. In heat transmission, this meaning has been extended to include both forced and natural motion or circulation.

Conventional Forging

A forging characteristic by design complexity and tolerances that fall within the broad range of general forging practice.

Conventional Milling

Milling in which the cutter moves in the direction opposite to the feed at the point of contact. Contrast with *climb milling*.

Conventional Strain

See *engineering strain* and *strain*.

Conventional Stress

The stress calculated on the original cross-sectional area, as opposed to the Real Stress. See *tensile test* and *engineering stress* and *stress*.

Convergent-Beam Electron Diffraction (CBED)

In *analytical electron microscopy*, a technique of impinging a highly convergent electron beam on a crystal to produce a diffraction pattern composed of disks of intensity. In addition to *d*-spacing and crystal orientation information, the technique can provide information on crystallographic point or space group symmetry.

Conversion Coating

(1) A coating consisting of a compound of the surface metal, produced by chemical or electrochemical treatments of the metal. Examples include chromate coatings on zinc, cadmium, magnesium, and aluminum, and oxide and phosphate coatings on steel. It forms a compound between the applied material and the base metal rather than merely depositing a layer. Anodizing, chromizing, and phosphating are examples. See also *chromate treatment* and *phosphating*.

Conversion Coatings

Surface transformations formed naturally by chemical or electrochemical methods on ferrous and nonferrous metals and alloys. *Natural conversion coatings*, usually oxides, include *rust*, the ferric oxide and hydroxide that forms on iron and plain carbon steels in air or moisture, and the adherent and protective oxides that forms on aluminum, copper, and other metals. *Chemical conversion coatings* are mainly phosphates, chromates, and oxides induced by the reaction of specific chemicals with metal surfaces. *Electrochemical conversion coatings* are formed by anodic oxidation, or anodizing, in an electrolytic cell in which the metal being treated is the anode.

Phosphate conversion coatings are formed on iron, steel, galvanized steel, and aluminum by chemicals containing phosphoric acid and its salts. *Zinc phosphates*, one of three major types, are applied by immersion or spray in a wide variety of coating weights and crystal sizes. The microstructure type enhances paint adhesion, minimizes paint consumption, and improves bonding to plastics and rubber.

The heavy kind are quite absorbent, thus capable of retaining forming lubricants and rust-preventive oils. They also reduce friction and enhance wear resistance and corrosion resistance. *Iron phosphates*, similarly applied, are produced from alkali-metal phosphate solutions. When amorphous or of fine crystal size, they are used mainly to improve paint adhesion and to increase resistance to paint flaking from impact or flexing. *Manganese phosphates*, applied only by immersion, are used to retain oil so as to facilitate part break-in and prevent galling of mating surfaces. Phosphate coatings have specific colors, depending on the chemicals used and the metal to which they are applied. Special colors can be developed by pretreatments and posttreatments.

Chromate conversion coatings are formed on aluminum, cadmium, copper, magnesium, silver, zinc, and their alloys by immersion or spray using aqueous solutions of chromic acid, chromium salts such as sodium or potassium chromate or dichromate, and hydrofluoric, phosphoric, or other mineral acids. Generally, the basic ingredients are hexavalent chromium and sufficient acid for the desired pH. Solutions of trivalent chromium are used for clear coatings on electroplated cadmium and zinc. Chromate-phosphate mixtures are used to produce combination coatings on aluminum. Chromates are typically amorphous, pore-free, and gel-like initially but, on drying, harden and become hydrophobic, less soluble, and more abrasion-resistant. They are used primarily to increase corrosion resistance, especially in marine, humid, and tropical atmospheres; but they also serve as a good base for paint. Various colors can be provided, depending on the particular solution and post-treatments. Regarding hexavalent chromium, however, the aim is to eliminate the use because of its carcinogenicity.

Oxide chemical conversion coatings are the bluish, black, or brown oxides formed on iron or steel with hot caustic or alkaline solutions, and the black or brown oxides formed on cadmium, copper, iron, steel, or zinc alloys with acidic solutions. Although they are used mainly for abrasion resistance and anesthetics, some add a modest degree of corrosion protection. Alkaline chromate solutions as fused-salt solutions, for example, impart corrosion resistance and abrasion resistance to iron and steel.

Electrochemical conversion coatings, or *anodic coatings*, pertain mainly to aluminum alloys or magnesium alloys, although several other metals are also anodized. Anodized aluminum is produced primarily in aqueous solutions of sulfuric, chromic, or oxalic acid for a variety of reasons; to improve corrosion resistance, abrasion resistance, paint adhesion, adhesive bonding, or electroplating; to provide decorative finishes, including color; and to impart an electrically insulative surface or a base for photographic or lithographic emulsions. *Hard anodic coatings* on aluminum alloys, for abrasion resistance, are typically thicker than those for corrosion protection. Anodized magnesium is produced in aqueous solutions of ammonium bifluoride, sodium dichromate, and phosphoric acid or in aqueous solutions of potassium and aluminum hydroxide, trisodium phosphate, potassium fluoride, and potassium manganate or permanganate. Thin coatings serve mainly as a base for paint, thick ones for corrosion resistance and abrasion resistance. Other nonferrous metals are anodized primarily to increase corrosion resistance. *Anodizing zinc* is produced by immersion in an alkali-carbonate solution and then in a silicate solution, or in a single alkaline solution of sodium silicate, borate, and tungstate. *Anodized beryllium* is made in an aqueous solution of nitric and chromic acids, and *anodized titanium* and *anodized thorium* are made in mixtures of glacial acetic and nitric acids. *Anodized zirconium* also has been made in such mixtures although, for nuclear applications it and *anodized hafnium* are made in aqueous solutions of ethanol, glycerine, and lactic, phosphoric, and citric acids, followed by autoclaving.

Anodized columbium and *anodized tantalum* are produced in solutions of ammonium citrate or borate, with ammonium hydroxide for basicity.

Conversion coatings are also known by various terms and trade names. Among the latter by Allied-Kelite, of Witco Corp., are *Keycote phosphate coatings*, *Iridite chromate coatings*, *Iridize zinc and anodic coatings*, and *Irilac clear coatings*. The clear coatings can be applied to the anodic for additional corrosion protection. Other terms and key ingredients applicable to hard-anodizing aluminum are Martin Hard Coat (sulfuric acid). *Magnaplate HCR*, of General Magnaplate, is a surface treatment to improve the hardness, corrosion resistance, and abrasion resistance of aluminum and aluminum alloys. *Nituff*, a Teflon-impregnated hard-anodized aluminum, combines hardness and lubricity which markedly increases release properties and wear resistance. One application is chemical polishing tubs used to make sapphire optics.

Converter

A furnace in which air is blown through a bath of molten metal or matte, oxidizing the impurities and maintaining the temperature through the heat produced by the oxidation reaction. A typical converter is the *argon oxygen decarbonization* vessel.

Convex Fillet Weld

A fillet weld having a convex face.

Convexity

The maximum distance from the face of a convex fillet weld perpendicular to a line joining the toes.

Cool Time (Resistance Welding)

The time interval between successive heat times in multiple-impulse welding or in the making of seam welds.

Coolants

Liquids used to quench metals in heat treating, used to cool and lubricate cutting tools and workpieces in machining, or applied to forming tools and workpieces to assist in forming operations. In the case of machining, they are also called *cutting fluids*, and in the case of forming, *forming lubricants*. When water is used for the normal water-hardening steels, it may be modified with soda or other material to give a less drastic and more uniform cooling. A water bath containing 5% sodium hydroxide gives uniform, rapid cooling. Oils are used in cooling or quenching baths to provide a more moderate cooling effect. Quenching oils are usually compounded, although fish oils alone are sometimes employed. Fish oils, however, have offensive odors when heated. Vegetable oils alone are likely to oxidize and become gummy. Animal oils become rancid. Lard and palm oils give low cooling rates, while cottonseed, neatsfoot, and fish oils give more rapid cooling. Mineral oils compounded with fish, vegetable, or animal oils are sold under trade names and vary considerably in their content. *Oil-quenching baths* are usually kept at a temperature of not over 150°F (66°C) by providing cooling pipes. *Tempering oils* differ from quenching oils only in that they are compounded to withstand temperatures up to about 525°F (274°C).

Coolants for machining are classified into five groups: straight oils, soluble oils, chemical coolants, synthetics, and semisynthetics. *Straight oils*, which contain no water, are petroleum or mineral oils with or without additional compounding. Without further compounding, they are suitable for light-to moderate-duty cutting on readily machined metals. For more severe machining, they are typically compounded with up to 20% fatty oils, sulfur, chlorine, phosphorus, or combinations thereof. Sulfur, chlorine, and phosphorus are commonly called *extreme-pressure additives* (EP additives). For the most severe applications, compounding, mainly with chlorine and sulfurized fatty oils, may exceed 20%. *Soluble oils*, such as emulsified sulfonated mineral oils, are also suitable for light- and moderate-duty applications. Although they do not match the straight oils in lubricity, they, like water-dilutable fluids in general, are better heat dissipators. Because of their water content, they are usually formulated with additives to prevent corrosion of the workpiece and to resist microbial degradation and souring, necessitating maintenance and service to retain these characteristics. Heavy-duty soluble oils are suitable for most applications for which straight oils are used. Chemical coolants were originally *amine nitrites*, but *amine borates* are commonly used now because nitrites in contact with amine form *nitrosamine*, a suspected carcinogen. They are noted for excellent cooling capacity, inhibiting corrosion, and resisting microbial degradation and souring. They have limited lubricity, however, and are confined to light-duty operations, mainly light grinding. *Synthetic coolants*, which have been likened to soluble oils without oil, are water-dilutable systems designed for high-cooling capacity, lubricity, corrosion prevention, and easy maintenance. These synthesized materials are chemically similar to mineral-oil derivatives, but can be dispersed in water and are suitable for more severe operations than chemical coolants. They tend to defat human skin, however, causing dermatitis, thus necessitating that workers adhere to prescribed methods of personal hygiene. *Semisynthetic coolants* contain small dispersions of oil in an otherwise water-dilutable system, are almost transparent, are more broadly applicable than soluble oils, and are easier to maintain.

Straight oils, soluble oils, and synthetics are also used as forming lubricants. They also may contain a *wetting agent*, or *polarity agent*, such as animal fats, fatty acids, long-chain polymers, emulsifiers, and EP additives. The straight oils are the most varied in formulation and the most widely used. The soluble oils, however, can match their performance in many applications and, because of their superior cooling effect, sometimes provide better performance. The synthetics, which have been improved in recent years, also feature excellent cooling capacity as well as cleanliness and lubricity, and they have replaced both the straight and soluble oils and many applications. Because of their cleanliness, they are especially useful in forming precoated metals.

Cooling Channels

In plastic part making, chemicals or passageways located within the body of a mold through which a cooling medium can be circulated to control temperature on the mold surface. May also be used for heating a mold by circulating steam, hot oil, or other heated fluid through channels, as in the molding of thermosetting and some thermoplastic materials.

Cooling Curve

A graph showing the relationship between time and temperature during the cooling of a material. It is used to find the temperatures at

which phase changes occur. A property or function other than time may occasionally be used—for example, thermal expansion.

Cooling Fixture

In plastic part making, block of metal or wood shape to hold a molded part to maintain the proper shape or dimensional accuracy of the part after it is removed from the mold until it is cooled enough to retain its shape without further appreciable distortion. Also called a shrink fixture.

Cooling Rate

The average slope of the time–temperature curve taken over a specified time and temperature interval.

Cooling Stresses

Residual stresses in castings resulting from nonuniform distribution of temperature during cooling.

Cooling Table

Same as a *hot bed*.

Coordinate Bonding

See *Interatomic Bonding*.

Coordination Catalysis

Ziegler-type of catalysis for processing plastics. See also *Ziegler–Natta catalysts*.

Coordination Compound

A compound with a central atom or ion bound to a group of ions or molecules surrounding it. Also called coordination complex. See also *chelate*, *complexation*, and *ligand*.

Coordination Number

(1) Number of items or radicals coordinated with the central atom in a complex covalent compound. (2) Number of nearest neighboring atoms to a selected atom and crystal structure. (3) It is 12 for the close packed hexagonal and face-centered cubic structures, and 8 for body centered cubic structures.

Cope

In casting, the upper or topmost section of a *flask*, *mold*, or *pattern*. The lower part is the drag.

Copolyesters

These thermoplastic elastomers are generally tougher over a broader temperature range than the urethanes. Also, they are easier and more forgiving in processing. Several grades include Hytrel, Riteflex, and Ecdel, ranging in hardness from 35 to 72 Shore D. These materials can be processed by injection molding, extrusion, rotational

molding, flow molding, thermoforming, and melt casting. Powders are also available.

Copolyesters, which along with the urethanes are high-priced elastoplastics, have excellent dynamic properties, high modulus, good elongation and tear strength, and good resistance to flex fatigue at both low and high temperatures. Brittle temperature is below -68°C , and modulus at -40°C is only slightly higher than at room temperature. Heat resistance of 449°C is good.

Resistance of the copolyesters to nonoxidizing acids, some aliphatic hydrocarbons, aromatic fuels, sour gases, alkaline solutions, hydraulic fluids, and hot oils is good to excellent. Thus, they compete with rubbers such as nitriles, epichlorohydrins, and polyacrylates. However, hot polar materials, strong mineral acids and bases, chlorinated solvents, phenols, and cresols degrade the polyesters. Weathering resistance is low but can be improved considerably by compounding ultraviolet stabilizers or carbon blacks with the resin.

Copolyester elastomers are not direct substitutes for rubber in existing designs. Rather, such parts must be redesigned to use the higher strength and modulus, and to operate within the elastic limit. Thinner sections can usually be used—typically one-half to one-sixth that of a rubber part.

Applications of copolyester elastomers include hydraulic hose, fire hose, power-transmission belts, flexible couplings, diaphragms, gears, protective boots, seals, oil-field parts, sports-shoe soles, wire and cable insulation, fiber-optic jacketing, electrical connectors, fasteners, knobs, and bushings.

Copolymer

A long-chain molecule formed by the reaction of two or more dissimilar monomers. See also *polymer*.

Copolymerization

See *polymerization*.

Copper Acetate

Also known as crystals of Venus. A dark-green, crystalline, poisonous powder. It is soluble in water and alcohol. It is used as a pigment in paints, lacquers, linoleum, and inks and for making artificial verdigris or patina on copper articles. It is used as a catalyst in making phthalic anhydride plastics. When used for mildew-proofing cotton cloth, the copper precipitates out to form the *waxate*, or copper soap coating. *Verdigris* is an old name for basic copper acetate as a blue-grain pigment, but the name is now usually applied to the bluish-green corrosion crust on copper. The greenish-brown crust known as patina, forms on bronze, is esteemed as a characteristic of antiquity. It is a basic sulfate of copper, usually with oxides of tin, copper, and lead.

Copper and Copper Alloys

Copper (symbol Cu) is one of the most useful of the metals, and probably the one first used by humans. It is found native and in a large number of ores. Its apparent plentifulness is only because it is easy to separate from its ores and is often a by-product from silver and other mining. Copper has a face-centered cubic crystal structure. It is yellowish red in color, tough, ductile, and malleable; gives a brilliant luster when polished; and has a disagreeable taste and a peculiar odor. It is the best conductor of electricity next to silver, with a conductivity 97% that of silver. Copper refers to the

metal at least 99.3% pure. Standard wrought grades number more than 50, many of which are more than 99.7% pure. They are represented by the C10XXX–C15XXX series of copper and copper alloy numbers of the Copper Development Association. These include O₂-free coppers, O₂-free-with-silver coppers, and O₂-bearing coppers (C11100–C10940); electrolytic-tough-pitch coppers and tough-pitch-with-silver coppers (C11100–C11907); phosphorus-deoxidizer coppers, fire-refined tough-pitch coppers (C12000–C13000); and certain coppers distinguished by very small amounts of specific ingredients such as cadmium copper (not to be confused with the high-copper alloys having a greater cadmium content), tellurium-bearing copper, sulfur-bearing copper, zirconium copper, and aluminum-bearing coppers (C14XXX–C15XXX). The highest-purity grade, O₂-free-electronic copper, is at least 99.99% pure. There are seven standard cast coppers (C80XXX–C81100); and their minimum purity ranges from 99.95% (C80100) to 99.70% (C81100).

O₂-free coppers (C10100 and C10200) have a melting point of 1082°C, a density of 8.94 mg/m³, an electrical conductivity of 101%—or slightly greater than the 100% for electrolytic-tough-pitch copper (C11100) used as the International Annealed Copper Standard (IACS) for electrical conductivity—a thermal conductivity of 391 W/m K, and a specific heat of 385 J/kg K. Typical tensile properties of thin flat products and small-diameter rod and wire having an average grain size of 0.050 mm are 220 MPa ultimate strength, 69 MPa yield strength, 45%–50% elongation, and 117,000 MPa elastic modulus. Hardness is about RF 40. These properties are fairly typical of other wrought coppers as well. Strength increases appreciably with cold work, yield strengths reaching 345 MPa in the spring and hard-drawn conditions. Zirconium copper, which may be heat-treated after cold working, can provide yield strengths of 345–483 MPa in rod and wire forms and retains considerable strength at temperatures to 426°C. Cast coppers are suitable for sand, plaster, permanent-mold, investment, and centrifugal castings as well as for continuous casting. Regardless of grade, typical tensile properties are 172 MPa ultimate strength, 48 MPa yield strength, and 40% elongation. Hardness is typically Brinell 44.

Copper and copper-base alloys are unique in their desirable combination of physical and mechanical properties. The following properties are found or may be developed in these materials:

1. Moderate to high strength and hardness
2. Excellent corrosion resistance
3. Ease of workability both in primary and secondary fabrication operations
4. Pleasing color and wide color range
5. High electrical and thermal conductivity
6. Nonmagnetic properties
7. Superior properties at subnormal temperatures
8. Ease of finishing by polishing, plating
9. Good-to-excellent machinability
10. Excellent resistance to fatigue, abrasion, and wear
11. Relative ease of joining by soldering, brazing, and welding
12. Moderate cost
13. Availability in a wide variety of forms and tempers

The importance of copper and copper-based alloys is in no small part because many other metals, whether singly or in combination, may be alloyed with copper. There are many binary alloys, and ternary and quaternary alloy systems which are quite common. The copper content of alloys in commercial use ranges from about 58% to about 100%. Alloys of 63% to about 100% copper are of the alpha (single-phase) solid solution type, have excellent ductility, and are ideally suited for cold-working processes such as rolling, drawing, and press working.

Copper alloys in the lower range, 62% and less, are of the alpha plus beta (two-phase) type and are particularly suited to hot-working processes such as hot rolling, hot extrusion, and hot forging.

The chief elements alloyed with copper are zinc, tin, lead, nickel, silicon, and aluminum, and to a lesser extent, beryllium, phosphorus, cobalt, boron, arsenic, zirconium, antimony, cadmium, iron, manganese, chromium, and very recently, mercury.

Cast Products

Foundry alloys are used in the form in which they are originally molded. In general, cast alloys are not easily workable and subsequent operations are limited to such treatment as machining, electroplating, soldering, and brazing. The use of alloys in cast form permits the production of intricate and irregular shapes impractical or impossible to make by other means. The use of cores permits the making of hollow shapes. The alloying metals are generally greater in amount than for wrought alloys. Types of castings in commercial use include sand castings, diecastings, permanent mold, plaster mold, shell mold, and centrifugal and investment castings. The alloy involved, the properties desired, and the quantity to be made govern the choice of casting process. Where regularity of shape permits, a number of foundry alloys are available in the continuous-cast condition and may be either solid or hollow shapes. The classification of copper-base foundry alloys generally follows that used for wrought alloys. As in the wrought-alloy field, the number of cast alloys in commercial use runs well into the hundreds; many are modifications of standard alloys.

Wrought Products

Wrought products are those originally cast into starting shapes such as billets, cakes (slabs), and wire bar, which are further fabricated into useful forms such as sheet, strip, plate, rod, bar, seamless tubes, extruded shapes, and forgings by hot rolling, cold rolling, cold drawing, hot piercing, hot extrusion, or combinations of these primary fabricating processes. Secondary fabricating processes include such operations as machining, bending, spinning, cold heading, hot press forging, soldering, brazing, electroplating, cold extrusion, and operations normally associated with press working (blanking, deep drawing, coining, staking, embossing, drifting).

The various types of copper and the copper-base alloys are not fabricated with equal facility into usable forms or by secondary fabricating processes. This fact, together with the wide range and combination of physical and mechanical properties desirable for end use, accounts for the large number of commercial wrought copper-base alloys. Design considerations usually dictate a compromise between service properties desired, secondary fabricating properties, forms and sizes available, and cost.

The Alloys

In the copper industry, and in the brass mill section of that industry in particular, the alloys of copper have been designated by a sort of “word-terminology” that is often confusing and misleading. Names assigned to various alloys are not always descriptive or indicative of the composition. Several names may be in common use for the same composition. Numerous proprietary names are also used and, in some cases, several names in this category are in general use for essentially the same composition or type of alloy.

Since the more important alloying elements are used effectively in varying amounts, a convenient and logical classification is made possible by separating the alloys into well-recognized groups

according to composition. Literally hundreds of wrought copper alloys are used. Those listed are standard alloys that account for the large majority of tonnage used. Alloys not listed are, in general, modifications of standard alloys often used for very special purposes.

Certain terms require clarification. Brass is an alloy of copper with zinc as the principal alloying element, used with or without additional elements. High brasses are Cu–Zn alloys containing more than 20% zinc, more properly called yellow brasses. Low brasses are alloys containing 20% zinc or less and low brass is a specific alloy, 80% copper and 20% zinc. Rich low brass is a term used for brass containing nominally 85% copper and 15% zinc, more properly called red brass. Straight brasses are those alloys containing copper and zinc only.

The term *bronze* in modern usage properly requires a modifying adjective. Early bronzes were alloys of copper with tin as the only, or principal, alloying metal, and thus the term *bronze* has been traditionally associated with alloys of copper and tin. The widespread use of numerous other alloy systems in recent times requires that a bronze be defined as an alloy of copper with some element, or elements, other than zinc as a chief alloying metal. Thus, “tin-bronze” is the proper name for alloys of copper and tin, silicon-bronze for alloys of copper and silicon, aluminum–silicon-bronze for an alloy of Cu–Al–Si. Tin-bronzes are also commonly called phosphor-bronzes because of the long-established practice of deoxidizing these alloys with phosphorus.

The “coppers” include pure copper and its modified forms, and also certain materials that might more properly be classed as alloys but that are commonly called “coppers” where the alloying element is less than about 1%, e.g., “TeCu”—0.5% tellurium, the balance, copper.

Refractory copper-base alloys are those that, because of their hardness or abrasiveness, require greater dimensional tolerances than those established for nonrefractory alloys. Examples of refractory alloys are the phosphor bronzes, silicon bronzes, aluminum bronzes, and nickel silvers.

Coppers

Many types and variations of commercial copper are available; the differences are slight or important depending upon the method of production or the intentional minor additions of other metals. Two types refer to the method of refining. Fire-refined copper is that finished by furnace refining. Electrolytically refined copper is that finished by electrolytic deposition where the original ore requires such refining because of certain undesirable impurities that can be satisfactorily removed only by this method, or where the original ore contains sufficient quantities of silver and gold, recoverable in electrolytic refining, to make the electrolytic process profitable. Over 85% of all copper is electrolytically refined. Three major types of commercial copper with respect to composition and method of casting are tough pitch, O₂-free, and phosphorus deoxidized. Tough-pitch copper contains a small but controlled amount of O₂ (about 0.04%) necessary to obtain a level set, i.e., the correct pitch, on the refinery casting (wire bar, cake, billet); the level set is necessary to provide adequate ductility for hot or cold primary fabricating operations, i.e., sufficient “toughness.” Electrolytic tough-pitch copper is the standard copper of industry for electrical and many other purposes. Its low electrical resistance (0.15328 Ω/g m² at 20°C) equivalent to 100% IACS conductivity is the standard with which other metals are compared. Copper has the highest conductivity of any base metal and is exceeded only by that of silver.

Tough-pitch copper has one distinct disadvantage. When heated above about 399°C in atmospheres containing reducing gases, particularly H₂, the CuO₂ is reduced to copper and water vapor, the water changing to steam at the temperatures involved, thus “gassing” or embrittling the copper and destroying its ductility. Hence, the term *H₂ embrittlement*. Under circumstances where H₂ embrittlement is likely to occur (brazing, welding, annealing), O₂-free copper may be used without sacrifice of conductivity. In cases where some conductivity loss may be tolerated, various types of deoxidized copper may be used. Tough-pitch copper, while ductile enough for most fabricating work, is somewhat lacking in the ductility required for difficult forming operations (severe drawing, edgewise heading) and O₂-free copper is often used in these instances. Also, tough-pitch copper is not as free machining as the varieties made for that purpose, i.e., leaded copper, TeCu, sulfur copper. Silver is added to copper (without sacrifice of conductivity) for the purpose of increasing the recrystallization temperature, thus permitting soldering operations without reduction of strength and hardness. The amount of silver added varies with the application. Lake copper is a general term for silver-bearing copper, having varying but controlled amounts of silver up to about 30 oz/ton.

Phosphorized copper, with excellent hot and cold workability, is the second largest type in use with respect to tonnage and is widely used for pipe and tube for domestic water service and refrigeration equipment.

O₂-free copper is made either by melting and casting copper in the presence of carbon or carbonaceous gases or by extruding compacted, specially prepared cathode copper under a protective atmosphere, so that no O₂ is absorbed. No deoxidizing agent is required; therefore, no residual deoxidants are present, and optimum electrical conductivity is maintained. O₂-free copper is used extensively in the electrical and electronics industries, e.g., metal-to-glass seals.

Wrought Cu Alloys

Copper and zinc melted together in various proportions produce one of the most useful groups of copper alloys, known as the brasses. Six different phases are formed in the complete range of possible compositions. The relationship between composition and phases alpha, beta, gamma, delta, epsilon, and eta are graphically shown in the well-established constitution diagram for the Cu–Zn system. Brasses containing 5%–40% zinc constitute the largest volume of copper alloys. One important alloy, cartridge brass (70% copper, 30% zinc), has innumerable uses, including cartridge cases, automotive radiator cores and tanks, lighting fixtures, eyelets, rivets, screws, springs, and plumbing products. Tensile strength ranges from 310 MPa as annealed to 900 MPa for spring temper wire.

Lead is added to both copper and the brasses, forming an insoluble phase that improves machinability of the material. Free cutting brass (61% copper, 3% lead, 36% zinc) is the most important alloy in the group. In rod form it has a strength of 340–480 MPa, depending on temper and size. It is machined into parts on high-speed (10,000 rpm) automatic screw machines for a multiplicity of uses.

Increased strength and corrosion resistance are obtained by adding up to 2% tin or aluminum to various brasses. Admiralty brass (70% copper, 2% aluminum, 0.023% arsenic, 21.97% zinc) are two useful condenser-tube alloys. The presence of phosphorus, antimony, or arsenic effectively inhibits these alloys from dezincification corrosion.

Alloys of copper, nickel, and zinc are called nickel silvers. Typical alloys contain 65% copper, 10%–18% nickel, and the remainder zinc. Nickel is added to the Cu–Zn alloys primarily because of its influence on the color of the resulting alloys; color ranges from

yellowish-white, to white with a yellowish tinge, to white. Because of their tarnish resistance, these alloys are used for table flatware, zippers, camera parts, costume jewelry, nameplates, and some electrical switch gear.

Copper forms a continuous series of alloys with nickel in all concentrations. The constitution diagram is a simple all alpha-phase system.

Nickel slightly hardens copper, increasing its strength without reducing its ductility. Copper with 10% nickel makes an alloy with a pink cast. More nickel makes the alloy appear white.

Three copper-base alloys, containing 10%, 20%, and 30% nickel, with small amounts of manganese and iron added to enhance casting qualities and corrosion resistance, are important commercially. These alloys are known as cupronickels and are well-suited for application in industrial and marine installations as condenser and heat-exchanger tubing because of their high corrosion resistance and particular resistance to impingement attack. Heat-exchanger tubes in desalinization plants use the cupronickel 10% alloy.

Cu–Sn alloys (3%–10% tin), deoxidized with phosphorus, form an important group known as phosphorus bronzes. Tin increases strength, hardness, and corrosion resistance, but at the expense of some workability. These alloys are widely used for springs and screens in papermaking machines.

Silicon (1.5%–3.0%), plus smaller amounts of other elements, such as tin, iron, or zinc, increases the strength of copper, making alloys useful for hardware, screws, bolts, and welding rods.

Sulfur (0.35%) and tellurium (0.50%) form insoluble compounds when alloyed with copper resulting in increased ease of machining.

Alloys of copper that can be precipitation-hardened have the common characteristic of a decreasing solid solubility of some phase or constituent with decreasing temperature. Precipitation is a decomposition of a solid solution leading to a new phase of different composition to be found in the matrix. In such alloys systems, cooling at the appropriate rapid rate (quenching) from an equilibrium temperature well within the all-alpha field will preserve the alloy as a single solid solution possessing relatively low hardness, strength, and electrical conductivity.

A second heat treatment (aging) at a lower temperature will cause precipitation of the unstable phase. The process is usually accompanied by an increase in hardness, strength, and electrical conductivity. Some 19 elements form copper-base binary alloys that can be age- or precipitation-hardened.

Two commercially important precipitation-hardenable alloys are Be–Cu and Cr–Cu. Be–Cu (2.0%–2.5% beryllium plus cobalt or nickel) can have a strength of 1400 MPa and an electrical conductivity of less than 50% of IACS. Cobalt adds high-temperature stability and nickel acts as a grain refiner. These alloys have found use as springs, diaphragms, and bearing plates and in other applications requiring high strength and resistance to shock and fatigue.

CuCr (1% chromium) can have a strength of 550 MPa and an electrical conductivity of 80%. Cu–Cr alloys are used to make resistance-welding electrodes, structural members for electrical switch gear, current-carrying members, and springs.

Cu–Ni, with silicon or phosphorus added, forms another series of precipitation-hardenable alloys. Typical composition is 2% nickel, 0.6% silicon. Strength of a 30 MPa can be obtained with high ductility and electrical conductivity of 32% IACS.

Zr–Cu is included in this group because it responds to heat treatment, although its strength is primarily developed through application of cold deformation or work. Heat treatment restores high electrical conductivity and ductility and increases surface hardness. Tensile strength of 500 MPa coupled with an electrical conductivity of 88% can be developed. Uses are resistance welding wheels

and tips, stud bases for transistors and rectifiers, commutators, and electrical switch gear.

As little as 2% beryllium content, combined with the thermal conductivity of copper, has improved wear resistance to extend mold life and accelerated mold cycle times. Advancements in electrode materials are directly responsible for use of alloys like Be–Cu in mold making.

Conventional EDM performance in Be–Cu alloys with graphite electrodes is similar to that of other copper work metals. However, differences in EDM performance for various grades of Be–Cu alloys are evident at all power levels.

Be–Cu alloys with beryllium contents of 0.2%–0.6% and 1.6%–2.0% have shown that the higher-content group exhibited improved conventional EDM performance over the lower-content group. Testing of EDM with Be–Cu must still be performed relative to the possible health hazards involving fumes or gases, which must be recognized. Adequate EDM tank ventilation and dust collection for machining particulates could eliminate the hazards of inhaling any free beryllium or copper.

Cast Copper Alloys

Copper alloy castings of irregular and complex external and internal shapes can be produced by various casting methods, making possible the use of shapes for superior corrosion resistance, electrical conductivity, good bearing quality, and other attractive properties. High-copper alloys with varying amounts of tin, lead, and zinc account for a large percentage of all copper alloys used in the cast form. Tensile strength ranges from 250 to 330 MPa depending on composition and size. Lead tin-bronzes with 6%–10% tin, about 1% lead and 4% zinc are used for high-grade pressure castings, valve bodies, gears, and ornamental work. Bronzes high in lead and tin (5%–25% lead and 5%–10% zinc) are mostly used for bearings. High tin content is preferred for heavy pressures or shock loading, but lower tin and higher lead is preferred for lighter loads, higher speeds, or where lubrication is less certain. A leaded red brass containing 85% copper and 5% each of tin, lead, and zinc is a popular alloy for general use.

High-strength bronzes containing 57%–63% copper, small percentages of aluminum and iron, and the balance zinc have tensile strengths from 490 to 830 MPa, high hardness, good ductility, and resistance to corrosion. They are used for valve stems and machinery parts requiring high strength and toughness.

Copper alloys containing less than 2% alloying elements are used when relatively high electrical conductivity is needed. Strength of these alloys is usually notably less than that of other cast alloys.

Aluminum bronzes containing 5%–10.5% aluminum, small amounts of iron, and the balance copper have high strengths even at elevated temperature, high ductility, and excellent corrosion resistance. The higher-aluminum-content castings can be heat-treated, increasing their strength and hardness. These alloys are used for acid-resisting pump parts, pickling baskets, valve seats and guides, and marine propellers.

Additives impart special characteristics. Manganese is added as an alloying element for high-strength bronzes where it forms intermetallic compounds with other elements, such as iron and aluminum. Nickel additions refine cast structures and add toughness, strength, and corrosion resistance. Silicon added to copper forms Cu–Si alloys of high strength and high corrosion resistance in acid media. Beryllium or chromium added to copper forms a series of age- or precipitation-hardenable alloys. Cu–Be alloys are among the strongest of the copper-base cast materials.

Copper Alloy Designations

Copper serves as the base metal for a great variety of wrought and cast alloys and the major wrought alloys and their designations, or alloy numbers, are high-copper alloys (C16200–C19750), which include CdCu, BeCu, and CuCr; CuZn brasses (C20500–C28580); Cu–Zn–Pb leaded brasses (C31200–C38590); Cu–Zn–Sn alloy or tin brasses (C40400–C49080); Cu–Sn phosphor bronzes (C50100–C52400); Cu–Sn–Pb bronze alloys or leaded phosphor bronzes (C53200–C54800); Cu–P alloys and Cu–Ag–P alloys (C55180–C55284); Cu–Al alloys or aluminum bronzes (C60600–C64400); Cu–Si alloys or silicon bronzes (C64700–C66100); miscellaneous Cu–Zn alloys (C66400–C69950); and Cu–Ni–Zn alloys or nickel silvers (C73150–C79900). All told, there are about 300 standard wrought alloys and many have cast counterparts (C81300–C99750). There are about 140 standard cast alloys. Many copper alloys are also available in powder form for powder-metal parts.

Cu–Ni wrought alloys are designated C70100–C72950; cast alloys, C96200–C96800. The alloys also have been referred to as cupronickels, Cu–Ni 20% (or whatever the percent nickel), also 80%–20% (or whatever the percent copper and nickel), nickel content may be as low as 2%–3% (C70200) or as high as 43%–46% (C72150), but intermediate amounts, nominally 10% (C70600 and C96200), 20% (C71000 and C96300), and 30% (C71500 and C96400), are the most common. Most of the alloys also contain small to moderate amounts of iron, zinc, manganese, and other alloying ingredients, and some contain substantial amounts of tin (1.8%–2.8% in C72500; 7.5%–8.5% in C72800).

The Brasses/Bronzes/Silvers/Cupronickels

The straight brasses are without question the most useful and widely used of all copper-base alloys. Zinc is used in substantial portions in five of the alloy groups listed. Most of the brasses are within the alpha field of the phase diagrams, thus maintaining good cold-working properties. With a higher zinc content of about 40%, the beta phase facilitates hot working. The addition of zinc decreases the melting point, density, electrical and thermal conductivities, and modulus of elasticity. It increases the coefficient of expansion, strength, and hardness. Work hardening increases with zinc content but 70–30 brass has the best combination of strength and ductility.

The low zinc brasses (20% zinc or less) have excellent corrosion resistance, are highly resistant to stress-corrosion cracking (SCC), and cannot dezincify. All of the low brasses are extensively used where these properties are required, along with good forming characteristics, and moderate strength. Commercial bronze is the standard alloy for domestic screen cloth, rotating bands on shells, and weatherstripping. Red brass is highly corrosion resistant, more so than copper in many cases, and is used for condenser tubes and process piping. The brasses have a pleasing color range varying from the red of copper through bronze and gold colors to the yellow of the high zinc brasses. The alloy 87.5% copper, 12.5% zinc very closely matches the color of 14-karat gold, and the low brasses in particular are used in inexpensive jewelry, for closures, and in other decorative items.

The high brasses, cartridge brass and yellow brass, have excellent ductility and high strength and have innumerable applications for structural and decorative parts that are to be fabricated by drawing, stamping, cold heading, spinning, and etching. Cartridge brass is able to withstand severe cold working in practically all fabricating operations, and derives its name from the deep-drawing operations necessary on small-arms munition cases, for which it is ideally suited. Muntz metal is primarily a hot-working alloy and

is cold-formed with difficulty. It is used in applications where cold spinning, drawing, or upsetting are not necessary. A typical use of Muntz metal is for condenser tube plates.

Silicon, Aluminum, and Manganese Brass

Silicon red brass has the corrosion resistance of the low brasses, with higher electrical resistance than that normally inherent in those brasses, and is especially suited to applications involving resistance welding. Aluminum brass is a moderate-cost alloy primarily made in tube form for use in condensers and heat exchangers, where its improved resistance to the corrosive and erosive action of high-velocity seawater is desired. Manganese brass serves the same purpose as silicon brass.

Leaded Brasses

The primary purpose in adding lead to any copper alloy is to improve machinability and related operations such as blanking or shearing. Lead also improves antifriction properties and is sometimes useful in that respect. Lead has an adverse effect in that both hot- and cold-working properties are hindered by reduced ductility. Optimum machinability is reached in free-cutting brass rod with 3.25% lead, ideally suited for automatic screw-machine work. Other leaded brasses in rod and other forms, with lead content ranging from 0.5% to over 2%, and with varying copper content, are available to permit varying combinations of corrosion resistance, strength, and hardness, and equally important, secondary fabricating processes (flaring, bending, drawing, stamping, thread rolling). Applications of all these alloys are found throughout industry.

Tin Brasses

Tin improves the corrosion resistance and strength of Cu–Zn alloys. Pleasing colors are obtainable when tin is alloyed with the low brasses. The tin brasses in sheet and strip form and with copper content of 80% or greater comprise a group of materials used as low-cost spring materials, for hardware, or for color effect alone, as in inexpensive jewelry, closures, and decorative items. Admiralty brass is the standard alloy for heat exchanger and condenser tubes, with good corrosion resistance to both seawater and domestic-water supplies. The addition of a small amount of antimony, phosphorus, or arsenic inhibits dezincification, a type of corrosion to which the high-zinc alloys are susceptible. Naval brass and manganese bronze are widely used for applications requiring good corrosion resistance and high strength, particularly in marine equipment for shafting and fastenings.

Phosphor Bronzes

As a group, these range in tin content from 1.25% to 10% nominal tin content. They have excellent cold-working characteristics, high strength, hardness, and endurance properties, low coefficient of friction, and excellent general corrosion resistance, and hence find wide use as springs, diaphragms, bearing plates, Fourdrinier wire, bellows, and fastenings.

Aluminum Bronzes

The alpha aluminum bronzes (containing less than about 8% aluminum) have good hot- and cold-working properties, while the alpha–beta alloys (8%–12% aluminum, with nickel, iron, silicon,

and manganese) are readily hot-worked. All have excellent corrosion resistance, particularly to acids, and high strength and wear resistance. Certain alloys in this category may be hardened by a heat-treatment process similar to that used for steels. Certain alloys in this group are used for spark-resistant tools.

Cupronickels

These are straight Cu–Ni alloys with nickel content ranging from 2.5% to 30% nickel and have increased corrosion resistance with increasing nickel content. Cupronickels are markedly superior in their resistance to the corrosive and erosive effects of high-velocity seawater. They are moderately hard but quite tough and ductile, so that they are particularly suited to the manufacture of tubes for condenser and heat-exchanger use, and have flaring, rolling, and bending characteristics necessary for installation.

Cadmium Bronzes

Alloys of copper and cadmium, with or without small additions of tin, are primarily used for electrical conductors where high electrical conductivity and improved properties are found.

Nickel Silvers

Actually nickel brasses, these alloys contain varying amounts of copper, zinc, and nickel. They have a color ranging from ivory white in the lower nickel alloys to silver white in the higher nickel alloys. Their pleasing silver color, coupled with excellent corrosion resistance and cold formability, makes them ideally suited as a base for silver-plated flatware and hollow-ware, and structural and decorative parts in optical goods, cameras, and costume jewelry. The low-copper 18% nickel alloy is used for springs and other applications where high fatigue strength is desired.

Silicon Bronzes

The silicon bronzes are an extremely versatile series of alloys, having high strength, exceptional corrosion resistance, and excellent weldability, coupled with excellent hot and cold workability. The low silicon bronzes (1.5% silicon) are widely used for electrical hardware. The high silicon bronzes are used for structural parts throughout industry. Al–Si bronze is an important modification with exceptional strength and corrosion resistance, particularly suited to hot working and with better machinability than the regular silicon bronzes.

Copper Alloy Powders

Besides copper, there are a rather large range of compositions of copper alloy powders available, including the brasses, bronzes, and Cu–Ni. Brass powders are the most widely used for powder-metal-lurgy structural parts. Conventional grades are available with zinc contents from around 10% to 30%. Sintered brass parts have tensile strengths up to around 245 and 280 MPa and elongations of from 15% to around 40% depending on composition, design, and processing. In machinability they are comparable in cost with wrought brass stock of the same composition. Brass P/M parts are well-suited for applications requiring good corrosion resistance, and where free machining properties are desirable.

Cu–Ni, or Ni–Ag, powders contain 10% or 18% nickel. Their mechanical properties are rather similar to the brasses, with slightly

higher hardness and corrosion resistance. Because they are easily polished, they find considerable use in decorative applications.

Copper and bronze powders are used for filters, bearings, and electrical and friction products. Bronze powders are relatively hard to press to densities to give satisfactory strength for structural parts. Probably the most commonly used bronze contains 10% tin. The strength properties are considerably lower than iron-base and brass powders, usually below 140 MPa.

Miscellaneous Copper Alloys

Narloy Z is a *copper–silver–zirconium* alloy for high temperature applications, such as vacuum-plasma-sprayed combustion chambers of rocket engines. It is also a candidate for engine inlets and wing leading edges of the U.S. national aerospace airplane. Powder-metal *copper–chromium–columbium* alloys Cu–8Cr–4Cb and Cu–6.5Cr–5.8Cb are also candidates for rocket-engine applications as well as heat exchangers, electrical contacts, and resistance welding electrodes. The latter alloy possesses high strength, creep resistance, and thermal conductivity at high temperatures. Besides their use for a great variety of parts, copper alloys are also used for surfacing ferrous and nonferrous parts for bearing applications, for corrosion and erosion resistance, and to rebuild worn parts. There are also *memory alloys*, or *shape-memory alloys*, which can be deformed and then revert to their original shape when heated to their transformation temperature. The reusable locknuts, from Memry Corp., are one application. With copper–aluminum–zinc or copper–aluminum–nickel alloy used for an answer, the insert can be deformed to lock the nut in place. When the nut is removed and heated to the alloys transformation temperature, the insert returns to its original shape so that the nut can be reused. An *89Cu–5Al–5Zn–1Sn* alloy, referred to as *Nordic Gold*, is used for several Euro coins. A series of *Thermitech copper–tungsten* alloys, from Mi-Tech Metals, Inc., are used for thermal heat sinks and electric circuits.

Copper Brazing

A term improperly used to denote brazing with a copper filler metal. See preferred terms *furnace brazing* and *brazing welding*.

Copper Loss

The power loss resulting from the resistance in electrical circuit.

Copper Matte

An intermediate stage in the production of copper from sulfide ores; it contains about two-thirds copper.

Copper Oxide

There are several oxides of copper but usually the term refers to *red copper oxide*, or *cuprous oxide*, Cu_2O , a reddish crystalline powder formed by the oxidation of copper at high temperatures. It also occurs naturally in cuprite ore. It is insoluble in water but soluble in acids and alkalis. It is used in coloring glass and ceramics red, in electroplating, and in alternating-current rectifiers. *Black copper oxide*, or *cupric oxide*, CuO , is a brownish-black amorphous powder. It is used for coloring ceramics green or blue. In its natural ore form, it is called tenorite. Together with the red oxide, it is used as a copper paint for ships' bottoms.

Cupric oxide, when used in glazes, has a wide range of color. It may be used either as the raw oxide in a raw glaze, as the raw oxide in a fritted glaze, or as part of the frit itself. Cupric oxide is generally preferred in glazes and cuprous oxide in glasses.

Copper hydroxide, formed by the action of an alkali on the oxides, is also a poisonous blue powder and is used as a pigment.

Copper Shortening

See *shortening*.

Copper Steel

Steel containing up to 0.25% copper and very low in carbon, employed for construction work where mild resistance to corrosion is needed and where the cost of the more resistant chromium steels is not warranted. It is employed in sheet form for culverts, ducts, pipes, and such manufacturing purposes as washing-machine boilers. The alloy steels containing considerable copper for special purposes are not classified as copper steels. The copper neutralizes the corroding influence of the sulfur in the steel and aids in the formation of a fine-grained oxide that retards further corrosion. Copper is not added to unalloyed high-carbon steels because it causes brittleness and hot-shortness. Since the carbon content of copper steel is usually very low, the material is more a copper iron. Unless balancing elements, especially nickel, are present, more than 0.2% copper in steel may cause rolling defects. Molybdenum in small quantities may also be added to give additional corrosion resistance, and the percentage of carbon may be raised to 0.40% when about 0.05% molybdenum is added.

Copper Sulfate

Also called *bluestone*, *blue copperas*, and *blue vitriol*. An azure-blue, crystalline, lumpy material. It is soluble in water and insoluble in alcohol. It is produced as a by-product in copper refineries, or by the action of sulfuric acid on copper or copper oxide. A major market for copper sulfate is agriculture, where it is used in fungicides, micronutrients for fertilizers and animal feeds, and seed treatment. In chemical processes, it is used as an algicide in water treatment, for separating sulfide ores, in electroplating, in froth flotation, in leather tanning and hide preservation, and as a raw material for other salts and dyes.

Copper-Accelerated Salt-Spray (CASS) Test

An *accelerated corrosion test* for some electrodeposits and for anodic or coatings on aluminum.

Copper-Constantan

A pair of metals used for thermocouples. See *Constantan*.

Copperhead

A reddish spot in a porcelain enamel coating caused by iron pickup during enameling, iron oxide left on poorly cleaned basic metal, or burrs on iron or steel basic metal that protrude through the coating and are oxidized during firing.

Cordierite

A talc-like mineral of composition $\text{Mg}_2\text{Al}_4\text{Si}_5\text{O}_{18}$ used in ceramics to make refractories, filters and diesel engines, and spark plug insulators. Cordierite has an unusually low coefficient of expansion ($1.4\text{--}2.6 \times 10^{-6}/^\circ\text{C}$ from 25°C to 1000°C) and high thermal shock resistance.

Core

(1) A specially formed material inserted in a mold to shape the interior other part of the casting that cannot be shaped as easily by the pattern. (2) To establish the internal shape of a hollow casting. (3) In a ferrous alloy prepared for *case hardening*, that portion of the alloy that is not part of the *case*. Typically considered to be the portion that (a) appears dark (with certain etchants) on an etched cross section (b) has an essentially unaltered chemical composition, or (c) has a hardness, after hardening, less than a specified value. (4) The central member of a *sandwich construction* (honeycomb material, foamed plastic, or solid sheet to which the faces of the sandwich are attached). (5) The inner material beneath a case hardened, or other surface layer. (6) The central mass of a transformer around which the windings are arranged.

Core (Plastics)

(1) In plastic part making, a channel in a mold for circulation of heat transfer media. (2) The part of a complex mold that molds undercut parts. Cores are usually withdrawn before the main sections of the mold are opened. Also called core pin.

Core Assembly

In casting, a complex score consisting of a number of sections.

Core Binder

In casting, any material used to hold the grains of core sand together.

Core Blow

A gas pocket in a casting adjacent to a cored cavity and caused by entrapped gases from the core.

Core Blower

A machine for making foundry cores using compressed air to blow and pack the sand into the core box.

Core Box

In casting, a wood, metal, or plastic structure containing a shaped cavity into which sand is packed to make a core.

Core Crush

A collapse, distortion, or compression of the core of a *sandwich construction*.

Core Depression

A localized indentation or gouge in the core of a *sandwich construction*.

Core Dryers

In casting, supports used to hold cores in shape during baking; constructed from metal or sand for conventional baking or from plastic material for use with the dielectric core-making equipment.

Core Filler

In casting, a material, such as coke, cinder, and sawdust, used in place of sand in the interiors of large cores; usually added to aid collapsibility.

Core Forging

(1) Displacing metal with a punch to fill a die cavity. (2) The product of such an operation.

Core Knockout Machine

In casting, a mechanical device for removing cores from castings.

Core Oil

In casting, a binder for core sand that sets when baked and is destroyed by the heat from the cooling casting.

Core Pin

In plastic part making, a pin used to mold a hole.

Core Pin Plate

In plastic part making, a plate holding core pins.

Core Plates

In casting, heat-resistant plates used to support cores during baking; may be metallic or nonmetallic, the latter being a requisite for dielectric core baking.

Core Plug

A plug inserted into the wall of a hollow casting to close a hole left by the core support or through which a sand core was extracted.

Core Print

In casting, projections attached to a pattern in order to form recesses in the mold at points where cores are to be supported.

Core Refining

The initial stage of hardening a carburized steel component. The carburizing treatment produces an undesirably large grain size in the component. Good quality work requires a fine grain size in both the low carbon core and the high carbon case. Initially, the component is heated to and quenched from about 880°C which is just within the austenitic region for the typical lower carbon core. This refines, hardens, and toughens the core. Subsequently, the component is heated to and quenched from about 750°C which is just

within the austenitic region for the high carbon case. This hardens the case. See *Steel* and *Case Hardening*.

Core Rod

In powder metallurgy, a member of a die assembly used in molding a hole in a compact.

Core Sand

In casting, sand for making cores to which a binding material has been added to obtain good cohesion and permeability after drying; usually low in clays.

Core Separation

In a *sandwich construction*, a partial or complete breaking of the core node bond.

Core Shift

In casting, a variation from the specified dimensions of a cored casting section due to a change in position of the core or misalignment of cores in assembly.

Core Splicing

The joining of segments of a core of a *sandwich construction* by bonding, or by overlapping each segment and then driving them together.

Core Vents

(1) In casting, a wax product, round or oval in form, used to form the vent passage in a core. Also, a metal screen or slotted piece used to form the vent passage in the core box used in a core blowing machine. (2) Holes made in the core for the escape of gas.

Core Wash

In casting, a suspension of a fine refractory applied to cores by brushing, dipping, or spraying to improve the surface of the cored portion of the casting.

Core Wires or Rods

(1) In casting, reinforcing wires or rods for fragile cores, often for preformed into special shapes. (2) (for welding) The central main wire of a continuous covered electrode.

Cored Bars

In powder metallurgy, a compact of bar shape heated by its own electrical resistance to a temperature high enough to melt its interior.

Cored Mold

In plastic part making, a mold incorporating passages for electrical heating elements, steam, or water.

Cored Solder

A solder wire or bar containing flux as a core.

Coreless Induction Furnace

An electric induction furnace for melting or holding molten metals that does not utilize a steel core to direct the magnetic field which stirs the melt.

Coring

(1) A condition of variable composition between the center and surface of a unit of microstructure (such as a dendrite, grain, carbide particle); results from nonequilibrium solidification, which occurs over a range of temperature. (2) A central cavity at the butt end of a rod extrusion, sometimes called *extrusion pipe*. (3) A variation in composition from center to edge of individual grains of an alloy solidifying as a solid solution. It is most pronounced where there is a large difference between the liquidus and the solidus and arises during casting because the first material to solidify is relatively rich in one element and the remaining molten material becomes progressively richer in the second element. The change in composition may be so extreme that a nonequilibrium phase precipitates in the latter stages of solidification. See Phase, Lever Rule and Solidification.

Coring (Plastics)

In plastic part making, the removal of excess material from the cross section of a molded part to attain a more uniform wall thickness.

Corner Angle

On face milling cutters, the angle between an angular cutting edge of a cutter tooth and the axis of the cutter, measured by rotation into an axial plane. See *face mill*.

Corner Joint

A joint between two members located approximately at right angles to each other in the form of an "L." Usually between 30° and 135°.

Corner-Flange Weld

A flange weld with only one member flanged at the location of welding.

Corona (Resistance Welding)

The area sometimes surrounding the nugget of a spot weld at the faying surfaces which provides a degree of solid-state welding.

Correction

In the case of a testing machine, the difference obtained by subtracting the indicated load from the correct value of the applied load.

Corrodkote Test

An *accelerated corrosion test* for electrodeposits.

Corrosion

Any process by which a metal reacts chemically or electrochemically with another element in the surrounding environment. It is usually implicit that the consequences will be damaging as opposed to processes such as anodizing. Damage includes loss of bulk section, pitting, rusting, and scaling. See also *Electrochemistry* and *Corrosion Resistance*.

Corrosion Effect

A change in any part of the *corrosion system* caused by *corrosion*.

Corrosion Embrittlement

Deeply penetrating corrosion damage, essentially cracking, often along grain boundaries. The damage is usually not obvious to a visual inspection but causes a major reduction in load carrying capacity not merely a reduction in toughness. See also *hydrogen damage*.

Corrosion Fatigue

A cracking mechanism in which corrosion and fatigue act concurrently to reduce significantly the total life that would be expected if fatigue loading and a corrosive environment had acted alone or consecutively. Purists sometimes argue that any fatigue, other than in vacuum, is corrosion fatigue. A more practical approach is to differentiate on the basis of the major difference in life seen in a clean and dry environment compared with that in a moist and contaminated one.

Corrosion Fatigue Strength

The maximum repeated stress that can be endured by a metal without failure under definite conditions of corrosion and fatigue and for a specific number of stress cycles and a specified period of time.

Corrosion Inhibitor

See *inhibitor*.

Corrosion Potential (E_{corr})

The electrical *potential* of a corroding surface in an electrolyte, relative to a *reference electrode*. Also called rest potential, open-circuit potential, or freely corroding potential.

Corrosion Product

Substance formed as a result of *corrosion*.

Corrosion Protection

Modification of a *corrosion system* so that corrosion damage is mitigated.

Corrosion Rate

Corrosion effect on a metal per unit of time. The type of corrosion rate used depends on the technical system and on the type

of corrosion effect. Thus, corrosion rate may be expressed as an increase and corrosion depth per unit of time (penetration rate, for example, mil/year) or the mass of metal turned into corrosion products per unit area of surface per unit of time (weight loss, for example, g/m²/year). The corrosion effect may vary with time and may not be the same at all points of the corroding surface. Therefore, reports of corrosion rates should be accompanied by information on the type, time dependency, and location of the corrosion effect.

Corrosion Resistance

The ability of a metal to avoid unacceptable reactions with its environment. For metals, this could be pitting or rusting; for organic materials, it could be crazing. Generalizing, metals can be divided into three categories. Some metals such as gold and platinum have inherent resistance, that is, they do not react to any significant extent with the atmosphere and many other environments. Other metals such as aluminum or titanium react very rapidly when exposed to the atmosphere but the oxide film is thin, tightly bonded to the metal and forms an impervious barrier to further attack. This is often termed Acquired Resistance. Finally, metals such as iron and steel in moist environments form a bulky, loosely adherent and porous oxide layer. This does not significantly slow the rate of attack and it may even detach, exposing bare metal for further attack. See also *stainless steel*.

Corrosion System

System consisting of one or more metals and all parts of the environment that influence *corrosion*.

Corrosion-Erosion

A combination of corrosion and erosion. There are considerable similarities with impingement attack and some authorities recognize only one mechanism. Where the two are differentiated, and this may not be easy in some cases, impingement is regarded as having a major electrochemical component arising from the potential difference between uncorroded areas and bare metal exposed by erosion. The term corrosion-erosion would then be confined to cases where the erosion merely serves to remove the products of corrosion which, if undisturbed, could impede further attacks. See also *Electrochemistry* and *Cavitation*. See also *erosion-corrosion*.

Corrosion-Resistant Alloys

There are now several corrosion-resistant alloys available that are capable of meeting most difficult design requirements.

Cast Alloys

In general, these are the cast counterparts to 3XX and 4XX wrought stainless steels and, thus, are also referred to as cast stainless steels. Designations of the Alloy Casting Institute of the Steel Founders Society of America and the wrought designations to which they roughly correspond (compositions are not identical) include CA-15 (410), CA-40 (420), CB-30 (431), CC-50 (446), CE-30 (312), CF-3 (304L), CF-3M (316L), CF-8 (304), CF-8C (347), CF-8M (316), CF-12M (316), CF-16F (303), CF-20 (302), CG-8M (317), CH-20 (309), and CK-20 (310). There are also other alloys that do not correspond to wrought grades. The cast

alloys corresponding to 3XX wrought grades have chromium contents in the range of 17%–30% and nickel contents in the range of 8%–22%. Silicon content is usually 2.00% maximum (1.50 for CE-8M), manganese 1.50% maximum, and carbon 0.08%–0.30% maximum, depending on the alloy. Other common alloying elements include copper and molybdenum. Those corresponding to 4XX grades may contain as much chromium but much less nickel; 1%–5.5%, depending on the alloy. Manganese and silicon contents are also generally less and carbon may be 0.15%–0.50%, depending on the alloy. All of the alloys are Fe–Cr–Ni alloys and the widest used are CF-8 and CF-8M, which limit carbon content to 0.08%. CN-7M and CN-7MS contain more nickel than chromium and, thus, are referred to as Fe–Cr–Ni alloys.

The alloys are noted primarily for their outstanding corrosion resistance in aqueous solutions and hot gaseous and oxidizing environments. Oxidation resistance stems largely from the chromium. Nickel improves toughness and corrosion resistance in neutral chloride solutions and weak oxidizing acids. Molybdenum enhances resistance to pitting in chloride solutions. Copper increases strength, and permits precipitation hardening to still greater strength. After a 482°C age, for example, the room-temperature tensile properties of CB-7Cu are 1290 MPa ultimate strength, 1100 MPa yield strength, 10% elongation, and 196, 500 MPa elastic modulus. Higher aging temperatures, to 621°C, decrease strength somewhat but markedly increase impact strength. The alloys are widely used for pumps, impellers, housings, and valve bodies in the power-transmission, marine, and petroleum industries, and for chemical, food, pulp and paper, beverage, brewing, and mining equipment.

Corrosive Flux

A flux with a residue that chemically attacks the base metal. It may be composed of inorganic salts and acids, organic salts and acids, or activated rosins or resins.

Corrosive Wear

Wear in which chemical or electrochemical reaction with the environment is significant. See also *oxidative wear*.

Corrosivity

Tendency of an environment to cause *corrosion* in a given *corrosion system*.

Corrugating

The forming of sheet metal into a series of straight, parallel alternate ridges and grooves with a rolling mill equipped with matched roller dies or a *press brake* equipped with a specially shaped punch and die.

Corundum

Corundum is a very hard crystalline mineral used chiefly as an abrasive, especially for grinding and polishing optical glass. It is in the alpha, or hexagonal, crystal form, usually containing some lime and other impurities. The physical properties are theoretically the same as for synthetic alpha Al₂O₃, but they are not uniform. The melting point and the hardness are generally lower because of impurities, and the crystal structure also varies.

Pure corundum is transparent and colorless, but most specimens contain some transition elements substituting for aluminum, resulting in the presence of color. Substitution of chromium results in a deep red color; such red corundum is known as ruby. The term *sapphire* is used in both a restricted sense for the “cornflower blue” variety containing iron and titanium, and in a general sense for gem-quality corundums of any color other than red.

Corundum is synthesized by a variety of techniques for use as synthetic gems of a variety of colors and as a laser source (ruby). The most important technique is the Verneuil flame-fusion method, but others include the flux-fusion and Czochralski “crystal-pulling” techniques. Native alumina occurring as rhombohedral crystals and also in masses and variously colored grains. Corundum and its artificial counterparts are abrasives especially suited to the grinding of metals.

Cosmetic Pass

A weld pass made primarily for the purpose of enhancing appearance.

Cosworth Process

A process for producing high-quality precision castings. Quality is assured by extreme efforts to avoid entrainment of oxide or other contaminants, in particular, by the use of extended periods of holding the molten metal followed by pumped, up-hill feeding. Precision is achieved by the use of molds of zircon sand having a low expansion coefficient.

Cottoning

The formation of web-like filaments of adhesive between the applicator and substrate surface.

Cottrell Process

Removal of solid particulates from gases with electrostatic precipitation.

Coulomb

The SI unit of quantity of electricity, the electrical charge transported by 1 A flowing for 1 s.

Coulomb Friction

A term used to indicate that the frictional force is proportional to the normal load.

Coulometer

An electrolytic cell arranged to measure the quantity of electricity by the chemical action produced in accordance with Faraday’s law.

Coulometry

In materials characterization, an electrochemical technique in which the total number of coulombs consumed in electrolysis is used to determine the amount of substance electrolyzed.

Coumarone

A colorless, oily liquid of composition C_8H_6O , used chiefly in making synthetic resins. It has a specific gravity of 1.096, is insoluble in water, and is easily oxidized. It can be reacted with butadiene to form an *indene-butadiene rubber* of superior properties. All of the *cumenes* are variants of benzene.

The indene resins are classified with the coumarone resins, but they are lighter in color and are used in varnishes. The coumarone resins are made by the action of sulfuric or phosphoric acid on coumarone, are very soluble in organic solvents and are used in lacquers, waterproofing compounds, molding, and adhesives.

Count

For fabric used in composites fabrication, the number of warp and filling yarns per inch and woven cloth. For yarn, size based on relation of length and weight.

Counterblock

A jog in the mating surfaces of dies to prevent lateral die shifting from side thrusts developed in forging irregularly shaped pieces.

Counterblow Equipment

Forging equipment with two opposed rams that are activated simultaneously to strike repeated blows on the workpiece placed midway between them.

Counterblow Forging Equipment

A category of forging equipment in which two opposed rams are activated simultaneously, striking repeated blows on the workpiece at a midway point. Action is vertical or horizontal.

Counterblow Hammer

A forging hammer in which both the *ram* and the *anvil* are driven simultaneously toward each other by air or steam pistons.

Counterboring

Removal of material to enlarge a hole for part of its depth with a rotary, pilot guided, end cutting tool having two or more cutting lips and usually having straight or helical flutes for the passage of chips and the admission of a cutting fluid.

Counterelectrode

In emission spectroscopy, the electrode that is used opposite to the self-electrode or supporting electrode and that is not composed of the sample to be analyzed. In voltammetry, the current between the working electrode and counterelectrodes is measured. See also *self-electrode*, *supporting electrode*, and *auxiliary electrode*.

Counterformal Surfaces

Surfaces whose centers of curvature are on the opposite sides of the interface, as in rolling-element bearings or gear teeth. In wear testing, this term is sometimes used to indicate that the test specimen

surfaces are not conformal (for example, with a sphere-on-flat or flat block-on-rotating ring configuration). In such cases, the nominal contact area of at least one of the test piece surfaces increases as the amount of wear increases. Contrast with conformal surfaces.

Countersinking

Beveling or tapering the work material around the periphery of a hole creating a concentric surface at an angle less than 90° with the centerline of the hole for the purpose of chamfering holes or recessing screw and rivet heads.

Couple

The ability of dissimilar metals in electrical contact to produce electrical currents. Similar effects can occur in a single component because of variations, from point-to-point, and the composition of the material or of the environment. See Thermoelectric Effects and *galvanic corrosion*.

Coupling

(1) The degree of mutual interaction between two or more elements resulting from mechanical, acoustical, or electrical linkage. (2) A device or mechanism joining two components or structures, usually for some specific function such as transmitting a fluid, traction or power or such purpose.

Coupon

A piece of material from which a test specimen is to be prepared—often an extra piece (as on a casting or forging) or a separate piece made from test purposes (such as a test weldment).

Covalent Bond

A bond in which two atoms share a pair of electrons. Contrast with *ionic bond*. See Interatomic bonding.

Cover Core

(1) In casting, a core set in place during the ramming of a mold to cover and complete a cavity partly formed by the withdrawal of a loose part of the pattern. Also used to form part or all of the cope surface of the mold cavity. (2) A core placed over another core to create a flat parting line.

Cover Half

The stationary half of a die-casting die.

Cover Pass

The final layer of a multilayer well. The term often implies a deposit having a good appearance.

Cover Plate (Welding Eye Protection)

A removable pane of colorless glass, plastic-coated glass, or plastic that covers the filter plate and protects it from weld splatter, pitting, or scratching when used in a helmet, hood, or goggles.

Covered Electrode

A composite filler metal electrode consisting of a core of a bare electrode or metal cored electrode to which a covering sufficient to provide a slag layer on the weld metal has been applied. The covering may contain materials providing such functions as shielding from the atmosphere, deoxidation, and arc stabilization and can serve as a source of metallic additions to the weld. See *electrode welding*.

Covering Power

(1) The ability of a solution to give satisfactory plating at very low current densities, a condition that exists in recesses and pits. This term suggests an ability to cover, but not necessarily to build up, a uniform coating, whereas *throwing power* suggests the ability to obtain a coating of uniform thickness on an irregularly shaped object. (2) The degree to which a porcelain enamel coating obscures the underlying surface. (3) The ability of a glaze to uniformly and completely cover the surface of the fired ceramic ware.

Crack

(1) A fracture type discontinuity characterized by a sharp tip and high ratio of length and width to opening displacement. (2) A line of fracture without complete separation. (3) A planar defect that has developed in an area that was substantially defect-free. There is often an implication of limited ductility and “Crack” as opposed to “break” tends to be favored where the component has not parted completely. See also *brake*, *rupture*, and *fracture*.

Crack Arrest Temperature

The temperature at which a running brittle fracture in steel will cease to propagate. The term may be used in connection with some particular laboratory test such as the Robertson Test. More generally the term refers to the lowest service temperature of a steel component at which a brittle fracture will not propagate further.

Crack Arrestor

Any feature, intended or otherwise, that stops a crack from propagating further. Such features may be on a microscopic scale, for example, nonmetallic inclusions, or on a macro scale, for example, reinforcement plates, ductile materials are even holes placed across the path of an advancing crack.

Crack Branching

The separation of a material into two or more segments.

Crack Extension (Δa)

An increase in crack size. See also *crack length*, *effective crack size*, *original crack size*, and *physical crack size*.

Crack Growth

Rate of propagation of a crack through a material due to a static or dynamic applied load.

C

Crack Initiator

Any feature, such as a crack, section change or inclusion, which has a local stress raising effect and hence assist the initiation of cracking by any mechanism.

Crack Length (Depth) (a)

In *fatigue* and *stress-corrosion cracking*, the *physical crack size* used to determine the crack growth rate and the *stress-intensity factor*. For a compact-type specimen, crack length is measured from the line connecting the bearing points of load application. For a center-crack tension specimen, crack length is measured from the perpendicular bisector of the central crack. See also *crack size*.

Crack Mouth Opening Displacement (CMOD)

See *crack opening displacement*.

Crack Opening Displacement (COD)

On a K_{Ic} specimen, the opening displacement of the notch surfaces at the notch and in the direction perpendicular to the plane of the notch and the crack. The displacement at the tip is called the crack tip opening displacement (CTOD), at the mouth, it is called the crack mouth opening displacement (CMOD). See also *stress-intensity factor* for definition of K_{Ic} . See *fracture toughness* and *fracture mechanics*.

Crack Plane Orientation

An identification of the plane and direction of a fracture in relation to product geometry. This identification is designated by a hyphenated code, the first letter(s) representing the direction normal to the crack plane and the second letter(s) designated the expected direction of crack propagation.

Crack Size (a)

A lineal measure of a principal planar dimension of a crack. This measure is commonly used in the calculation of quantities descriptive of the stress and displacement fields. In practice, the value of crack size is obtained from procedures for measurement of *physical crack size*, *original crack size*, or *effective crack size*, as appropriate to the situation under consideration. See also *crack length (depth)*.

Crack Tip Opening Displacement (CTOD)

See *crack opening displacement*.

Cracked Gas

A generic term for a gas mixture obtained by thermal decomposition, with or without catalysis, of a gaseous compound. Examples: cracked ammonia (NH_3) is a mixture of nitrogen and hydrogen, and cracked natural gas hydrocarbons such as methane (CH_4) are a mixture of carbon and hydrogen. Cracked ammonia is also known as *disassociated ammonia*.

Crack-Extension Force (G)

The elastic energy per unit of new separation area that would be made available at the front of an ideal crack in an elastic solid during

a virtual increment of forward crack extension. This definition is useful for either static cracks or running cracks. From past usage, crack extension force is commonly associated with linear-elastic methods of analysis. See also *J-integral*.

Crack-Extension Resistance (K_R)

A measure of the resistance of a material to *crack extension* expressed in terms of the *stress-intensity factor*, the *crack-extension force*, or values of J derived from the *J-integral* concept.

Cracking

In lubrication technology, that process of converting unwanted long-chain hydrocarbons to shorter molecules by thermal or catalytic action. See *fracture toughness* and *fracture mechanics*.

Crackled

Either a craze cracked surface or a severely wrinkled paint coating.

Crack-Tip Plane Strain

A stress-strain field near a crack tip that approaches plane strain to the degree required by empirical criterion.

Crank

Forging shape generally in the form of a "U" with projections at more or less right angles to the upper terminals. Crank shapes are designated by the number of *throws* (for example, *two-throw* crank).

Crank Press

A mechanical press whose slides are actuated by a crankshaft.

Crankpin Bearing

See *big-end bearing*.

Crater

In arc welding, a depression or hole at the termination of a weld bead or in the molten weld pool resulting from local shrinkage during solidification.

Crater Crack

A crack in the crater of a weld bead.

Crater Fill Time

The time interval following weld time but prior to meltback time during which arc voltage or current reaches a preset value greater or less than welding values. Weld travel may or may not stop at this point.

Crater Fill Voltage

The arc voltage value during crater fill time.

Crater Wear

The wear that occurs on the rake face of a cutting tool due to contact with the material in the chip that is sliding along that face.

Cratering

Depressions on coated plastic surfaces caused by excess lubricant. Cratering results when paint is too thin and later ruptures, leaving pinholes and other voids. Use of less thinner in the coating can reduce or eliminate cratering, as can less lubricant on the part.

Craze Cracking

Irregular surface cracking of a metal associated with thermal cycling. This term is used more in the United Kingdom than in the United States, where the term checking is used instead.

Crazing

Multiple intersecting surface cracks, usually shallow, arising from various causes but particularly thermal shock.

Crazing (Ceramics)

The cracking which occurs in fired glazes or other ceramic coatings due to critical tensile stresses.

Crazing (Plastics)

Region of ultrafine cracks, which may extend in a network on or under the surface of a resin or plastic material. May appear as a white band. Often found in a filament-wound pressure vessel or bottle. In many plastics, craze growth precedes crack growth because crazes are load bearing.

Creel

In composites fabrication, a spool, along with its supporting structure, that holds the required number of roving balls or supply packages in a desired position for unwinding for the next processing step, that is, weaving, braiding, or filament winding.

Creep

Time-dependent strain occurring under stress. The creep strain occurring at a diminishing rate is called primary creep; that occurring at a minimum and almost constant rate, secondary creep; and that occurring at an accelerating rate, tertiary creep.

Creep Ductility

The elongation at failure of a component failing by creep. See Creep.

Creep Limit

(1) The maximum stress that will cause less than a specified quantity of creep in a given time. (2) The maximum nominal stress under which the creep strain rate decreases continuously with time under constant load and at constant temperature. (3) This term has a range of interpretations and some potential for confusion. The most basic definition is the maximum stress that can be allowed without causing unacceptable damage. Damage, in the context of Creep Limit, may

be defined as failure or as some level of Strain, in which cases it is necessary also to specify the service temperature and life required. Damage may also be specified as a rate of deformation in which case only the temperature need be specified. See Creep. Sometimes used synonymously with *creep strength*.

Creep Permanent

Progressive deformation, occurring over a period of time, at loads below the yield stress. Most metals at ambient temperature will carry a stress which is less than the yield stress for, effectively, an indefinite period; when the stress is removed the component will revert to its original dimensions. However, if the temperature of the component is raised above a critical level any significant stress will, over a period of time, cause progressive deformation that remains after the stress has been removed. If the load is maintained for a sufficient period internal voids and cracks will develop and ultimately the component will fail. A typical, perhaps idealized, creep test has the characteristics three stage, strain to time relationship, termed a Creep Curve. In the usually brief primary, or transient stage, deformation is rapid as it is dominated by mechanisms such as dislocation movement and grain boundary slide, i.e., the two neighboring grain faces rotating across each other. This high initial rate then slows as work hardening plays an increasing role. In the longer secondary, or steady-state stage, deformation continues at a lower uniform rate arising from the balance between work hardening and thermal softening. Toward the end of this stage, damage, in the form of grain boundary voids, starts to become visible under the microscope. In the final tertiary or runaway stage, deformation accelerates as voids join up, gross grain boundary cracks develop and the specimen necks prior to failure. This conventional view of creep being accompanied by major deformation is often confirmed by service experience but it is not universal; some metals fail by creep with negligible reduction in area and only a fraction of one percent elongation. Such behavior may be termed Creep Brittle. Creep failure is often termed Creep Rupture but this does not imply any special characteristic of failure; it could equally be termed "creep fracture" or even "creep breakage" although these phrases tend to sound inappropriate to most metallurgists. The temperature at which creep commences is broadly related to the melting point of the metal, it often being suggested that creep of pure metals is significant above half their absolute temperature melting point. For example, lead will creep, at least over decades or centuries, at normal ambient temperature and mild steel will creep at a significant rate above about 400°C. The rate of damage, above the critical temperature, rises with increasing stress and temperature. Creep deformation characteristics, often termed the Stress Rupture Properties, are determined by testing specimens of the material over ranges of stresses and temperatures to establish the time to reach a specified percentage creep strain or to fail. Unfortunately, the results obtained from testing identical specimens under identical conditions are rarely the same. Hence, the results of numerous tests plotted on a graph do not form a neat smooth curve but tend to be scattered over a fairly wide band. This gives rise to such terms as Creep Scatter Band while designs may be made on the basis of Lower Scatter Band (i.e., the lower line enclosing all test results) or 90% Scatter Band (the line enclosing 90% of all results) or Average Stress Rupture properties. See also Stress Rupture and Larsen Miller Parameter for examples of creep data presentation.

Creep Rate

The slope of the creep-time curve at a given time. Deflection with time under a given static load.

C

Creep Recovery

The time-dependent decrease in strain in a solid, following the removal of force.

Creep Relaxation

The reduction of imposed load as a result of deformation by creep, i.e., by the conversion of elastic strain to plastic strain by a creep mechanism. The phenomenon occurs in assemblies where the loading mechanism is rigid and does not move sufficiently to maintain the stress. One example is high temperature bolts which are tightened to induce a large amount of tensile elastic extension while the flange through which they pass, being of much larger cross section, experiences negligible elastic compression. If the bolt creeps, assuming it does not fail, the joint closure force will progressively fall. This contrasts with the case of, for example, a boiler tube which experiences a constant internal pressure. If the tube distends the internal pressure remains the same but is carried by a reducing wall thickness so the stress rises. See also preload and displacement control.

Creep Rupture

Failure by Creep. See also Larsen Miller Parameter.

Creep Strain

The time-dependent total strain (extension plus initial gauge length) produced by applied stress during a creep test.

Creep Strength

(1) The stress that will cause a given *creep strain* in a creep test at a given time in a specified constant environment. (2) Generally, the strength of the material in its creep range. More specifically, the same as creep limit.

Creep Stress

The constant load divided by the original cross-sectional area of the specimen.

Creep Test

A method of determining the extension of metals under a given load at a given temperature. The determination usually involves the plotting of time–elongation curves under constant load; a single test may extend over many months. The results are often expressed as the elongation (in millimeters or inches) per hour on a given gauge length (e.g., 25 mm or 1 in.).

Creep-Feed Grinding

See *grinding*.

Creep-Rupture Embrittlement

Embrittlement under creep conditions of, for example, aluminum alloys and steels that results in abnormally low rupture ductility. In aluminum alloys, iron and amounts above the solubility limit is

known to cause such embrittlement; in steels, the phenomenon is related to the amount of impurities (for example, phosphorus, sulfur, copper, arsenic, antimony, and tin) present. In either case, failure occurs by *intergranular cracking* of the embrittled material.

Creep-Rupture Strength

The stress that causes fracture in a creep test at a given time, in a specified constant environment. This is sometimes referred to as the stress-rupture strength. In glass technology, this is termed the static fatigue strength.

Creep-Rupture Test

A test in which progressive specimen deformation and the time for rupture are both measured. In general, deformation is much greater than that developed during a creep test. Also known as stress-rupture test.

Creosote

Also called *dead oil* and *pitch oil*. A yellowish, poisonous oily liquid obtained from the distillation of coal tar. It has the odor of carbolic acid. The crude creosote oil is used as a wood preservative and as a harsh disinfectant, but its use in these applications is expected to decrease because it has been recently classified as a possible carcinogen. Other applications include use as a fluxing oil for coal-tar pitch and bitumen, production of carbon black, and use in sprays for dormant fruit plants. Creosote is also obtained in the distillation of pinewood tar and is then a yellowish liquid with a smoky odor, a mixture of phenols and derivatives.

Crescent Crack

Damage having the appearance of a crescent, produced in a glass surface by the frictional translation of a hard, blunt object across the glass surface. The crescent shape is concave toward the direction of translation on the damage surface.

Crevice Corrosion

(1) *Localized corrosion* of a metal surface at, or immediately adjacent to, an area that is shielded from full exposure to the environment because of close proximity between the metal and the surface of another material. (2) Corrosion, occurring within a narrow gap which is severe compared with that on a plain surface exposed to the same environment. The mechanism usually involves the development of variations in environment composition from point to point leading to electrochemical corrosion. The variation may be a concentration effect, for example, of dissolved salts, or it may be a depletion effect, for example, a reduction in oxygen within the crevice.

Crimping

(1) The formation of circumferential corrugations around one side of a tube to induce a bend, more usually termed wrinkle bending. (2) The deliberate kinking of a folded lap joint to lock the joint. (3) The introduction of angular ridges in a sheet surface to improve rigidity. (4) The introduction of multiple transverse indentations in bar to improve grip or to increase its length. See also *corrugating*.

Critical Anodic Current Density

The maximum anodic current density observed in the active region for a metal or alloy electrode that exhibits active-passive behavior in an environment.

Critical Cooling Rate

The minimum rate of continuous cooling for preventing undesirable transformations. For steel, unless otherwise specified, it is the slowest rate at which austenite can be cooled from above critical temperature to prevent its transformation above the martensite start temperature. See *steels*.

Critical Current Density

In an electrolytic process, a current density at which an abrupt change occurs in an operating variable or in the nature of an electrodeposit or electrode film.

Critical Curve

In a binary or higher order *phase diagram*, a line along which the phases of a heterogeneous equilibrium become identical.

Critical Damping

In dynamic mechanical measurement of plastics, that damping required for the borderline condition between oscillatory and non-oscillatory behavior.

Critical Diameter

Diameter of a steel bar that can be fully hardened with 50% martensite at its center.

Critical Dimension

A dimension on a part that must be held within the specified tolerance for the part to function in its application. A noncritical tolerance may be for cost or weight savings or for manufacturing convenience, but is not essential for the products.

Critical Flaw Size

The size of a flaw (defect) in a structure that will cause failure at a particular stress level.

Critical Frequency/Speed

The vibration frequency or rotational speed which coincides with a natural resonance frequency of the component. At this critical condition, perturbations which would normally be innocuous can rapidly increase in severity leading to damage or failure. Examples include gross instability of shafts, collapse of bridges, and rapid fatigue failure of turbine blades. Design and operating practices therefore aim to avoid completely, or to pass rapidly through, the critical stage.

Critical Humidity

The *relative humidity* above which the atmospheric corrosion rate of some metals increases sharply.

Critical Illumination

In metallography, the formation of an image of the light source in the object field.

Critical Length

In composites fabrication, the minimum fiber length required for shear loading to its ultimate strength by the matrix.

Critical Longitudinal Stress

The longitudinal stress necessary to cause internal slippage and separation of a spun yarn and a fiber-reinforced plastic. The stress necessary to overcome the interfiber friction developed as a result of twist.

Critical Mass

The minimum amount of fissile material required to sustain nuclear fission.

Critical Micelle Concentration

The concentration of a micelle at which the rate of increase of electrical conductance with increase in concentration levels off or proceeds at a much slower rate. See also *micelle*.

Critical Pitting Potential (E_{cp} , E_p , E_{pp})

The lowest value of oxidizing potential at which pits nucleate and grow. It is dependent on the test method used.

Critical Point

(1) The temperature or pressure at which a change in crystal structure, phase, or physical properties occurs. Also termed *transformation temperature*. (2) In an equilibrium diagram, that combination of composition, temperature, and pressure at which the phases of an inhomogeneous system are in equilibrium.

Critical Pressure

That pressure above which the liquid and vapor states are no longer distinguishable.

Critical Rake Angle

The rake angle in which the action of a V-point tool changes from cutting to plowing. See also *rake*.

Critical Range

In steels it is temperature range between the upper critical and lower critical temperatures. See *steel*.

Critical Shear Stress

The shear stress required to cause slip in a designated slip direction on a given slip plane. It is called the critical resolved shear stress if the shear stress is induced by tensile or compressive forces acting on the crystal.

C

Critical Strain

The minimum amount of plastic strain, i.e., deformation, required to induce recrystallization. Some metals, such as iron, can develop a completely new grain structure by heating them through a phase transformation. However, in the absence of such a transformation, a metal cannot form a new structure by heating below the melting point, unless it has been plastically deformed by more than a critical amount, the critical strain, typically a few percent. This process of developing a new grain structure with associated reduction in the hardness is termed annealing and, generalizing, the more severe the deformation the finer the subsequent grain size. Consequently, components deformed only slightly more than the critical amount can form structures with exceptionally large grain sizes when annealed. This effect is termed *critical strain grain growth*. (1) In mechanical testing, the strain at the yield point. (2) The strain just sufficient to cause recrystallization. Recrystallization takes place from only a few nuclei, which produces a recrystallized structure consisting of very large grains.

Critical Strain Energy Release Rate

The toughness as measured by the energy input required for a crack to continue propagating.

Critical Stress Intensity Factor

See *stress-intensity factor* and *fracture toughness*.

Critical Surface

In a ternary or higher order *phase diagram*, the area upon which the phases in equilibrium become identical.

Critical Temperature

That temperature above which the vapor phase cannot be condensed to liquid by an increase in pressure. Synonymous with *critical point* if pressure is constant.

Critical Temperature Range

Synonymous with transformation ranges, which is the preferred term.

Criticality of a Nuclear Reactor

The state at which the fission reaction is exactly in balance with the number of neutrons released being just sufficient to maintain the chain reaction.

Croning Process

In casting, a shell molding process that uses a phenolic resin binder. Sometimes referred to as *C* process or *Chronizing*.

Crop

(1) An end portion of an ingot that is cut off as scrap. (2) To shear a bar or billet.

Cropping

The practice of cutting off and discarding the ends of bars, ingots, etc., as these are the site of defects.

Cross Breaks

Same as *coil breaks*.

Cross Direction

See *transverse direction*.

Cross Forging

Preliminary working of forging stock in flat dies to develop mechanical properties, particularly in the center portions of heavy sections.

Cross Laminate

In composites fabrication, a laminate in which some of the layers of material are oriented approximately at right angles to the remaining layers with respect to the grain, or strongest direction in tension. A bidirectional laminate. See also *parallel laminate*.

Cross Link

Intermolecular bonds produced between long-chain molecules in a material to increase molecular size and weight by chemical or electron bombardment, resulting in a change in physical properties in the material, usually improved properties.

Cross Linking

With thermosetting and certain thermoplastic polymers, the setting up of chemical links between the molecular chains. When extensive, as in most thermosetting resins, cross-linking makes an infusible supermolecule of all the chains. In rubbers, the cross-linking is just enough to join all molecules into a network.

Cross Rolling

Rolling of metal or sheet or plate so that the direction of rolling is about 90° from the direction of a previous rolling.

Cross Slip

The extension of a dislocation from one slip plane to an adjacent plane.

Cross-Country Mill

A rolling mill in which the mill stands are so arranged that their tables are parallel with a transfer (or crossover) table connecting them. Such a mill is used for rolling structural shapes, rails, and any special form of bar stock not rolled in the ordinary bar mill.

Crossed Joint

See *bridging*.

Cross-Linking, Degree of

The fraction of cross-linked polymeric units in the entire system.

Cross-Ply Laminate

A laminate with plies usually oriented at 0° and 90° only.

Cross-Roll Straightener

A machine having paired rolls of special design for straightening round bars or tubes, the pass being made with the work parallel to the axes of the rolls.

Cross Section

(1) Of a bar, extrusion, etc., it is the shape and dimensions of the face formed by a full transverse cut. (2) In the context of nuclear interactions it is a function of the probability that a particle entering the material in question will meet a particle with which to react. The SI unit is the barn.

Cross-Wire Weld

A weld made at the junction between crossed wires or bars.

Crosswise Direction

In testing of plastics, crosswise refers to the cutting of specimens and to the application of load. For rods and tubes, crosswise is any direction perpendicular to the long axis. For other shapes or materials that are stronger in one direction than in another, crosswise is the direction that is weaker. For materials that are equally strong in both directions, crosswise is an arbitrarily designated direction at right angles to the lengthwise direction.

Crowfoot Satin

In this type of composite fabric weave, there is a three-by-one interlacing; that is, a filling thread floats over three warp threads and then under one. This type of fabric looks different on one side than the other. Fabrics with this weave are more pliable than either the *plain* or *basket weave* and, consequently, are easier to form around curves.

Crown

(1) The upper part (head) of a forming press frame. On hydraulic presses, the crown usually contains the cylinder; on mechanical presses, the crown contains the drive mechanism. See also *hydraulic press* and *mechanical press*. (2) A shape (crown) ground into a flat roll to ensure flatness of cold (and hot) rolled sheet and strip. (3) A contour on a sheet or roll where the thickness or diameter increases from edge to center.

Crucible

A vessel in which metal is melted.

Crucible Furnace

A melting or holding furnace in which the molten metal is contained in a pot-shaped (hemispherical) shell. Electric heaters or fuel-fired burners outside the shell generate the heat that passes through the shell (crucible) to the molten metal.

Crucible Steel

The term is sometimes still used to refer to steels made in small quantities and, possibly, claimed to have superior characteristics.

Cruciform

Having the geometry of a cross. A cruciform weld joint is formed when two bars or plates are welded in the same plane on either side of, and perpendicular to, another plate. A cruciform test is one in which such a joint is made, inspected and, usually, tested to destruction.

Crud

Originally an American term for solid particulate contamination in the boiler water of steam power plants. The term is now used for any solid suspension or deposition in any liquid.

Crush

(1) Buckling or breaking of a section of a casting mold due to incorrect register when the mold is closed. (2) An indentation in the surface of a casting due to displacement of sand when the mold was closed. (3) In a split-journal bearing, the amount by which a bearing half extends above the horizontal split of the bore before it is assembled. Also known as *nip* in the United Kingdom.

Crush Forming

Shaping a grinding wheel by forcing a rotating metal roll into its face so as to reproduce the desired contour.

Crushed Strip or Bead

In casting, an indentation in the *parting line* of a pattern plate that ensures that *cope* and *drag* will have good contact by producing a ridge of sand that crushes against the other surface of the mold or core.

Crushing

A process of comminuting large pieces of metal or ore into rough size fractions prior to grinding into powder. A typical machine for this operation is a jaw crusher.

Crushing Test

(1) A radial compressive test applied to tubing, sintered-metal bearings, or other similar products for determining radial crushing strength (maximum load in compression). (2) An axial compressive test for determining quality of tubing, such as soundness of weld and welded tubing.

Cryogenic Treatment

See *cold treatment*.

Cryogenics

Today's limited acceptance and use of deep-cryogenic treatment at liquid N₂ temperature (−196°C) is usually attributed to a lack of understanding of the technology, as well as to the absence of generally acceptable practices for deploying it.

When the above two factors are resolved the “science” of deep cryogenics and its potential contributions will be shown. For example, a deep-cryogenic treatment at −196°C between quenching and tempering optimizes the mechanical properties of AISI T15 high-speed steel and dramatically improves its wear resistance, compared with standard heat treatments that do not incorporate a cryogenic step.

When the above is used, deep cryogenics does indeed become a science—results are predictable and the mechanical properties of the heat-treated parts are optimized. This is why it is believed that the use of the process during heat treating should now be standard rather than optional.

In future heat-treating guidelines and practices and procedures it is recommended that when using deep cryogenics as part of the heat treatment, the temperature of the subsequent temper be noted for the specific steel and the hardness vs. tempering temperature.

Cryolite

A mineral of composition Na₃AlF₆, found in commercial quantities in Greenland and used as a flux in the electrical production of aluminum, and the making of special glasses and porcelain, as a binder for abrasive wheels, and in insecticides. It acts as a powerful flux because of its solvent power on silicon, aluminum, and calcium oxides. In opal and milky classes, it forms a complex AlF₆ anion, retaining the alumina and preventing loss of the fluorine.

Cryopump

A type of vacuum pump that relies on the condensation of gas molecules and atoms on internal surfaces of the pump, which are maintained at extremely low temperatures.

Crystal

(1) A solid composed of atoms, ions, or molecules arranged in a pattern that is repetitive in three dimensions. (2) That form, or particle, or piece of a substance in which its atoms are distributed in one specific orderly geometrical array, called “lattice,” essentially throughout. Crystals exhibit characteristic optical and other properties and growth or cleavage surfaces, in characteristic directions. (3) “Crystal” is often interchangeably with grain. Unfortunately, there are no widely accepted rules to guide usage but, generalizing, “crystal” tends to be favored in the context of features on an atomic scale, for example crystal lattice, whereas “grain” tends to be favored for larger scale matters, for example grain size. Note however, “Crystalline” is used, when describing a fracture surface, to indicate a bright angular faceted appearance resulting from cleavage along specific crystallographic planes, characteristic of brittle fracture. See *crystal structure*.

Crystal Analysis

A method for determining crystal structure, for example, the size and shape of the unit cell and the location of all atoms within the unit cell.

Crystal Lattice

See *crystal structure*.

Crystal Orientation

See *orientation*.

Crystal Structure

The arrangement of atoms in crystals including virtually all solid metals. Atoms in crystals are arranged in simple, repeating, three-dimensional patterns rather than in the random jumble of amorphous, i.e., noncrystalline, materials. The basic unit of the pattern can be visualized as comprising atoms located at specific points on a simple geometric body, for example the points of the cube. This concept leads to terms such as “Body Centered Cubic” or “Face Centered Cubic” in which atoms lie on the points of the cube and also, respectively, at the center of the body or the center of each face. The basic block is repeated for very large distances, measured on an atomic scale, and the atoms can then be regarded as lying in layers or on atomic planes. The three-dimensional arrangement is termed a lattice. An individual crystal or grain has all of its atoms and atomic planes in continuous alignment. Neighboring crystals will have the same patterns but their planes will not be in alignment. The interfaces between grains are referred to as the crystal boundaries or grain boundaries. Also see *ordering* and *dislocations*.

Crystal System

One of seven groups into which all crystals may be divided; triclinic, monoclinic, orthorhombic, hexagonal, rhombohedral, tetragonal, and cubic.

Crystalline

(1) That form of a substance which is comprised predominantly of (one or more) crystals, as opposed to glassy or amorphous. (2) A bright, angular faceted fracture surface. See *crystal*.

Crystalline Fracture

A pattern of highly reflecting crystal facets on the fracture surface of a polycrystalline metal, resulting from *cleavage fracture* of many individual crystals. Contrast with *fibrous fracture*, and *silky fracture*; see also *granular fracture*.

Crystalline Plastic

A material having an internal structure in which the atoms are arranged in an orderly three-dimensional configuration. More accurately referred to as a semicrystalline plastic because only a portion of the molecules are in crystalline form.

Crystallinity (Plastics)

A regular arrangement of the atoms of a solid in space. In most polymers, including cellulose, this state is usually imperfectly achieved. The crystalline regions (ordered regions) are submicroscopic volumes in which there is some degree of regularity in the arrangement of the component molecules. In these regions there is sufficient geometric order to obtain definite x-ray diffraction patterns.

Crystallite

An imprecise term which may mean no more than a very small crystal. Alternatively, the term may refer to sub crystals within a grain or small crystals or parts of crystals which do not exhibit all of the characteristics of a crystal.

Crystallization

(1) The separation, usually from a liquid phase on cooling, of a solid crystalline phase. (2) The progressive process in which crystals are first nucleated (started) and then grown in size within a host medium which supplies their atoms. The host may be gas, liquid, or of another crystalline form.

Crystallographic Cleavage

The separation of a crystal along a plane of fixed orientation relative to the three-dimensional crystal structure within which the separation process occurs, with the separation process causing the newly formed surfaces to move away from one another in directions containing major components of motion perpendicular to the fixed plane.

Crystallography

The study of crystal structure.

Crystobalite

An allotropy of quartz. See *quartz*.

C-Stage

In processing of plastics, the final stage in the reaction of certain thermosetting resins in which the material is practically insoluble and infusible. Also called *resite*. The resin in a fully cured thermoset molding is in this stage. See also *A-stage* and *B-stage*.

CTE Mismatch

The difference in the coefficients of thermal expansion (CTEs) of two materials or components joined together, producing strains and stresses at the joining interfaces or in the attachment structures (solder joints, leads, and so on).

CTOD

See *Cracking Opening Displacement*.

CTS

(1) Compact tension specimen. See *fracture toughness*. (2) Controlled thermal severity test.

Cube Texture

A texture found in wrought metals in the cubic system in which nearly all the crystal grains have a plane of the type (100) parallel or nearly parallel to the plane of working and a direction of the type (100) parallel or nearly parallel to the direction of elongation.

Cubic

Having three mutually perpendicular axes of equal length.

Cubic Boron Nitride (CBN)

An extremely hard ceramic material synthesized by high-pressure sintering of hexagonal *boron nitride*. CBN is used in the machining and grinding of ferrous material such as tool steels, cast irons, hard-facing alloys, and surface-hardened steels. See also *superabrasives*.

Cubic Close Packed

See *close packed hexagonal*.

Cubic Plane

A plane perpendicular to any one of the three crystallographic axes of the cubic (isometric) system; the *Miller Indices* are (100).

Cull

Plastic material in a transfer chamber after the mold has been filled. Unless there is a slight excess in the charge, the operator cannot be sure the cavity is filled. Charge is generally regulated to control thickness of the cull.

Cumulative Damage

The total amount of damage resulting from a number of damage mechanisms or from a number of exposures to a mechanism. The term is commonly used in the case of fatigue reflecting the variation and stress range or other variables that a component might experience. The basic concept in all cases is that each exposure consumes a fraction of the fatigue life and failure will occur when these fractions total unity.

Cumulative Erosion–Time Curve

A plot of cumulative erosion vs. cumulative exposure duration, usually obtained by periodic interruption of the erosion test and weighing of the specimen. This is the primary record of an erosion test used to derive other characteristics such as incubation period, maximum erosion rate, terminal erosion rate, and the erosion rate–time curve.

Cup

(1) A sheet metal part; the product of the first drawing operation. (2) Any cylindrical part or shell closed at one end.

Cupellation

Oxidation of molten lead containing gold and silver to produce lead oxide, thereby separating the precious metals from the base metal. The rate of oxidation is usually increased by an air jet.

C

Cupola

A vertical shaft, air blast furnace, lined with refractory, for remelting, in particular, cast iron. The charge of iron with metallurgical coke or charcoal as fuel and a flux are introduced at the top; the molten iron and slags are tapped at the bottom.

Cupping

(1) The first step in deep drawing. (2) Fracture of severely worked rods or wire where one end has the appearance of a cup and the other that of a cone.

Cupping Test

A mechanical test used to determine the ductility and stretching properties of sheet metal. It consists of measuring the maximum part depth that can be formed before fracture. The test is typically carried out by stretching the test piece clamped at its edges into a circular die using a punch with a hemispherical end. See also *Erichsen test*, *Olson ductility test*, and *Swift cup test*.

Cupronickel

Copper-based alloys containing significant amounts of nickel.

Cure

(1) To change the physical properties of a material (usually from a liquid to a solid) by chemical reaction or by the action of heat and catalysts, alone or in combination, with or without pressure. (2) To irreversibly change, usually at elevated temperatures, the properties of a thermosetting resin by chemical reaction, that is, by condensation, ring closure, or addition. Cure may be accomplished by the addition of curing (cross linking) agents, with or without heat and pressure.

Cure Cycle

The time/temperature/pressure cycle used to cure a thermosetting resin system or prepreg.

Cure Monitoring, Electrical

Use of electrical techniques to detect changes in the electrical properties and/or mobility of the resin molecules during cure. A measuring of resin cure.

Cure Stress

A residual internal stress produced during the curing cycle of a composite structure. Normally, these stresses originate when different components of a wet lay-up have different thermal coefficients of expansion. One Curie is the quantity of radionuclide in which the number of disintegrations in 1 s is 3.7×10^{10} .

Curie Point/Temperature

For a metal, it is the temperature below which is magnetic (more strictly ferromagnetic) and above which it is nonmagnetic (paramagnetic). For iron it is 770°C.

It is also the temperature at which piezoelectric materials lose their electromechanical characteristics. See also *ferromagnetism* and *paramagnetism*.

Curing Agent

A catalytic or reactive agent that causes cross linking of a plastic. Also called a hardener.

Curing Temperature

The temperature to which an adhesive or an assembly is subjected to cure the adhesive. The temperature attained by the adhesive in the process of curing (adhesive curing temperature) may differ from the temperature of the atmosphere surrounding the assembly (assembly curing temperature). See also *drying temperature* and *setting temperature*.

Curing Time

In plastic part making, the time between the instant of cessation of relative movement between the moving parts of a mold and the instant that pressure is released. Also called molding time.

Curing Time (No Bake)

In foundry practice, the period of time needed before a sand mass reaches maximum hardness.

Curling

Rounding the edge of sheet metal into a closed or partly closed loop.

Current

The net transfer of electric charge per unit time. Also called electric current. See also *current density*.

Current Decay

In spot, seam, or projection welding, the controlled reduction of the welding current from its peak amplitude to a lower value to prevent excessively rapid cooling of the weld nugget.

Current Density

The current in amps, flowing to or from a unit area of the electrode surface.

Current Efficiency

(1) The ratio of the electrochemical equivalent current density for a specific reaction to the total applied current density. (2) The proportion of current used in a given process to accomplish a desired result; in electroplating, the proportion used in depositing or dissolving metal. See *Faraday's Law*.

Current-Carrying Capacity

The maximum current that can be carried continuously, under specified conditions, by a conductor without causing objectionable degradation of electrical or mechanical properties.

Curtain Coating

A method of coating that may be employed with low-viscosity resins or solutions, suspensions, or emulsions of resins in which the substrate to be coated is passed through and perpendicular to a freely falling liquid curtain (or waterfall). The flow rate of the falling liquid and the linear speed of the substrate passing through the curtain are coordinated in accordance with the thickness of coating desired.

Curvature of Field

In metallography, a property of a lens that causes the image of a plane to be focused into a curved surface instead of a plane.

Cushion

Same as *die cushion*.

Cut

In lubricant technology, a product or fraction obtained by distillation within a specified temperature range.

Cut (Foundry Practice)

(1) To recondition molding sand by mixing on the floor with a shovel or blade-type machine. (2) To form the sprue cavity in a mold. (3) Defect in a casting resulting from erosion of the sand by metal flowing over the mold or cored surface. (4) Apart from obvious meanings it often implies the depth of cut at a single pass of the cutting tool.

Cut Edge

A mechanically sheared edge obtained by slitting, shearing, or blanking.

Cut Layers

With laminated plastics, a condition of the surface of machines or ground rods and tubes and of sanded sheets in which cut edges of the surface layer or lower laminations are revealed.

Cut-and-Carry Method

Stamping method wherein the part remains attached to the strip or is forced back into the strip to be fed through the succeeding stations of a progressive die.

Cutlery Steel

Originally approximately 1% carbon steel used for domestic cutlery and other blades but now usually 12% chromium, 0.3% carbon (martensitic stainless steel).

Cut-Off (Casting)

Removing a casting from the sprue by refractory wheel or saw, arc-air torch, or gas torch.

Cut-Off (Metal Forming)

A pair of blades positioned in dies or equipment (or a section of the die milled to produce the same effect as inserted blades) used to separate the forging from the bar after forging operations are completed. Used only when forgings are produced from relatively long bars instead of from individual, precut multiples or blanks. See also *blank* and *multiple*.

Cut-Off (Plastics)

The line where the two halves of a mold come together. Also called groove and pitch-off.

Cut-Off Wheel

A thin disk, coated or impregnated with abrasive, rotating at high speed and often water cooled, for cutting purposes. It can produce a narrow, clean-cut with minimal surface damage even in hard materials. Also variously termed cutting wheel, slitting wheel, elastic wheel, etc.

Cutting Alloys

Usually of complex Co–Cr–W–Fe–Si–C composition, used for lathes and planer tools for cutting hard metals. They form a class distinct from the cemented carbides, which are not true alloys; from the refractory hard metals, which are chemical compounds; and from the cobalt high-speed steels, which are high in iron and usually have less carbon. The hardness is inherent in the alloy and is not obtained by heat treatment, as with the tool steels. Cutting alloys are cast to shape and are usually marketed in the form of tool bits and shear blades. Complex alloys, however, may have heat-transition points at which the metal complexes change structure, limiting the range of use.

Since the development of balanced high-speed steels and cermet-type cutting tools, these alloys with a high proportion of the scarcer cobalt have lost their importance as cutting alloys and, because of their high corrosion, heat, and wear resistance, are used chiefly for weld-facing rods and heat-corrosion applications. The first of the commercial cobalt cutting alloys was *Stellite*, of Haynes Stellite Co., in various composition grades and with trade names, such as *J-metal* and *Star J-metal*. Other similar alloys contain boron for added wear resistance. This type of alloy is now used in *surgical alloys* for surgical tools and dental plates since they are not attacked by body acids and set up no electromotive currents. To make them more workable for this purpose, they usually contain a higher content of cobalt, 60% or more, with a smaller amount of molybdenum instead of tungsten, and with less carbon and silicon.

Cutting Attachment

A device for converting an oxyfuel gas welding torch into an oxygen cutting torch.

Cutting Compound/Fluid/Paste

A substance applied at the cutting edge during machining. Where it is a stream of fluid its primary function is cooling but all of these substances act as a lubricant and limit adhesion to the tool edge. They also contribute to surface finish, tool life and precision.

C

Cutting Down

Removing roughness or irregularities of a metal surface by abrasive action.

Cutting Edge

The leading edge of a cutting tool (such as a lathe tool, drill or milling cutter) where a line of contact is made with the work during machining. See *single-point tool*.

Cutting Fluid

A fluid used in metal cutting to improve finish, tool life, or dimensional accuracy. On being flowed over the tool and work, the fluid reduces friction, the heat generated, and tool wear, and prevents galling. It conducts the heat away from the point of generation and also serves to wash the *chips* away.

Cutting Head

The part of a cutting machine or automatic cutting equipment in which a cutting torch or tip is incorporated.

Cutting Nozzle

See preferred term *cutting tip*.

Cutting Process

A process which brings about the severing or removal of metals. See also *arc cutting* and *oxygen cutting*.

Cutting Speed

The linear or peripheral speed of relative motion between the tool and workpiece in the principal direction of cutting.

Cutting Tip

That part of an oxygen cutting torch from which the gases issue.

Cutting Tools

Polycrystalline diamond (PCD) and polycrystalline cubic boron nitride (PCBN) inserts could be the best means of increasing productivity despite their high cost. In the past, PCD and PCBN cutting tools were difficult to cost-justify, unless they were essential for the machining job.

Today, improvements in quality and reliability make these tools, although still costly, competitive in many machining applications in the automotive, aerospace, and medical equipment industries. More rigid machines and tooling setups enable manufacturers to take full advantage of the potential for improved productivity offered by PCD and PCBN inserts. Also, having more cutting-tool options gives manufacturing engineers an opportunity for cost-effective productivity improvement in various machining applications.

PCBN

New, thicker PCBN solid inserts with larger grain size possess improved wear and impact resistance—the key to effective

machining of materials like cast irons containing less than 10% ferrite content. Such performance improvement is especially important when machining alloy cast irons for automotive applications. Previously, manufacturers had to grind these castings.

In roughing operations on alloy cast irons, tools must withstand interrupted cuts due to surface cracks, sand inclusions, and other surface discontinuities inherent to the casting process. Good wear resistance comes into play in finishing operations, where parts containing 28%–30% chromium have a hardness between R_c 68 and R_c 72.

Solid PCBN inserts provide multiple cutting edges on two sides, reducing insert cost per part produced. PCBN inserts also come in *full-face* and *tipped* types. The full-face type has a complete PCBN top face sintered onto a carbide substrate, and provides multiple cutting edges on one side only. These inserts are less expensive than solid PCBN inserts. The tipped style contains a small PCBN segment brazed onto one corner of a carbide insert, providing either a single cutting edge or double cutting edges. Most PCBN inserts used today are tipped. Both full-face and tipped PCBN inserts come in industry-standard sizes and, like the solid insert, can be used in the insert pockets of standard tool-holders and milling cutters.

Inserts made of PCBN work best in hard-part machining applications. In practice, the low end for part hardness falls at about R_c 45. Machining softer parts using PCBN produces insert cratering.

In roughing operations, maximum depths of cut using solid-style PCBN inserts range from about 4.76 mm for white iron and other hard, high-chromium irons to about 6.4 mm for unalloyed, “clean” cast irons. Finishing speeds range from 107 to 122 m/min on high-chromium irons to as high as 2134 m/min on gray cast irons. All PCBN operations require the use of very rigid tooling, work fixturing, machine spindles, and machine tools.

Currently, the largest growth area for PCBN inserts is in hard turning/finish turning of alloy steel automotive engine components such as gears, shafts, and bearings with hardnesses between R_c 60 and R_c 65. Traditionally, manufacturers ground these parts to obtain very tight dimensional tolerances and a fine surface finish. Hard turning gives the same results using a CNC lathe.

Insert edge preparation also strongly influences the success of PCBN machining. To promote good tool life, a reinforced cutting edge with the proper edge preparation is a must.

PCD

PCD inserts are cost-effective because they dramatically outperform carbide in most nonferrous applications, not because of any developments in the material itself.

Most PCD inserts used today are tipped. They employ a small segment of PCD brazed onto one corner of a carbide insert. PCD inserts come in industry-standard sizes for use in the insert pockets of standard tool-holders and milling cutters. Unlike carbide inserts, however, PCD-tipped inserts are not indexable, and provide only a single cutting-edge.

Standard-size, full-face-style PCD inserts provide a complete PCD top face sintered onto a carbide substrate.

More secure insert retention—especially in rotating tools—has played a key role in increasing the use of PCD inserts. Today’s combinations of wedges and screws, as well as tapered inserts and wedges, enhance insert retention. Conventional screw or clamp designs, and cutters using direct-mount cartridges where the PCD segment is brazed directly onto the cartridge body, also provide the necessary rigidity. Rigid tooling setups provide more reliable results with PCD.

More secure part fixturing and more rigid machine tools and spindles also improve performance. Today’s CNC lathes and machining centers provide all the rigidity required by PCD or PCBN

cutting tools. And as companies install new equipment, the machine shop environment becomes more suited to high-performance PCD and PCBN cutting tools.

Cutters used for finish milling of aluminum automotive manifolds often combine PCD-tipped and plain carbide inserts to cut through the casting flash encountered at the insert depth-of-cut line.

Another major use of PCD-tipped inserts is roughing automotive parts in a process called “cubing.” Foundries economize on shipping costs and recover aluminum chips for recycling by rough machining castings such as aluminum cylinder heads. They then semifinish the castings (top, bottom, side, and edge) at very high metal-removal rates using a PCD cutting tool. Machined parts are easier to handle and pack because of their rectangular shape, and shipping costs are lower for the smaller parts because they take up less space.

PCD-tipped inserts are preferred over carbide in applications where manufacturers want higher production rates, consistent part finish, and longer tool life (eliminating frequent tool changes). These inserts excel in machining abrasive high-silicon aluminum automotive parts like cylinder heads, engine blocks, manifolds, transmission cases, and wheels.

When using PCD inserts, good chip evacuation is essential. Because the inserts produce chips so rapidly, the system must remove them from the work zone quickly and continuously. Coolant, air, mist, refrigerated air, or combinations of all these methods will work. PCD cutting speeds as high as 3048 m/min are possible with effective chip evacuation and a rigid machine and operating set up. Today’s CNC machining and turning centers easily achieve these speeds.

Cutting Torch (Oxyfuel Gas)

A device used for directing the preheating flame produced by the controlled combustion of fuel gases and to direct and control the cutting oxygen.

Cutting Torch (Plasma Arc)

A device used for plasma arc cutting to control the position of the electrode, to transfer current to the arc, and to direct the flow of plasma and shielding gas.

Cutting Wear

See *abrasive wear*.

CVD Carbon

See *chemical vapor deposited (CVD) carbon*.

Cyanate Resins

Thermosetting resins that are derived from bisphenols or polyphenols, and are available as monomers, oligomers, blends, and solutions. Also known as cyanate esters, cyanic esters, and triazine esters.

Cyanic Copper

Copper electrodeposited from an alkali-cyanide solution containing a complex ion made up of univalent copper and the cyanide radical; also the solution itself.

Cyanide Slimes

Finely divided metallic precipitates that are formed when precious metals are extracted from their ores using cyanide solutions.

Cyaniding

A case-hardening process in which a ferrous material is heated above the lower transformation temperature range at about 900°C in a molten salt containing cyanide to cause simultaneous absorption of carbon and nitrogen at the surface and, by diffusion, create a concentration gradient. *Quench hardening* completes the process. See *case hardening*.

Cyanoacrylate

A thermoplastic monomer adhesive characterized by excellent polymerizing and bonding strength.

Cycle

One complete operation of a plastic molding press from closing time, for example, in one cycle to closing time in the next cycle.

Cycle (N)

In fatigue, one complete sequence of values of applied load that is repeated periodically. See also *S–N curve*.

Cycle Annealing

An annealing process employing a predetermined and closely controlled time–temperature cycle to produce specific properties or microstructures.

Cycle Hydrocarbons

Cyclic or ring compounds; benzene (C₆H₆) is a classic example.

Cyclic Load

(1) Repetitive loading, as with regularly recurring stresses on a part, that sometimes leads to fatigue fracture. (2) Loads that change value by following a regular repeating sequence of change.

Cyclic Stressing

See *cyclic load*.

Cyclone

In powder metallurgy, a collector of fractions of a powder from air, water, or other gases or liquids; the device operates with the aid of centrifugal force that acts on the powder suspension in the fluid.

Cylinder Manifold

See preferred term *manifold*.

Cylindrical Grinding

Grinding the outer cylindrical surface of a rotating part.

Cylindrical Land

Land having zero relief.

Taylor & Francis

Taylor & Francis Group

<http://taylorandfrancis.com>

D

D

Dalic Process

A portable electroplating system in which the plating solution is delivered through suitable pads or brushes.

Dalton's Atomic Theory

In essence, this stated that matter is comprised of atoms that are discrete, indivisible particles. All atoms of an element are the same. Chemical reactions are the result of atoms combining in simple proportions. Although it has subsequently been demonstrated that atoms can be divided into smaller particles and isotopes have been discovered, the general principles are the basis of chemistry.

Dam

In composites fabrication, a boundary support or ridge used to prevent excessive edge bleeding or resin runout of a laminate and to prevent crowning of the bag during cure.

Damage Tolerance

(1) A design measure of crack growth rate. Cracks in damage-tolerant designed structures are not permitted to grow to critical size during expected service life. (2) The ability of a part component, such as an aerospace engine, to resist failure due to the presence of flaws, cracks, or other damage for a specified period of usage. The damage tolerance approach is used extensively in the aerospace industry.

Damascening

The repeated folding and forge welding of layers of steel. Individual layers have varying carbon contents, deliberately or otherwise, which show as light and dark areas after polishing and etching to provide a decorative finish. The word derives from Damascus where the technique was used for high-quality swords and other blades. Generalizing, the greater the number of repetitions of folding and forging, the finer becomes the decorative effect and the stronger and tougher becomes the steel.

Damping

The loss in energy, as dissipated heat, that results when a material or material system is subjected to an oscillatory load or displacement.

Damping Capacity

(1) The ability of a material to absorb vibration (cyclical stresses) by internal friction, converting the mechanical energy into heat. (2) An induced strain where energy is dissipated internally. Materials having a low-damping-capacity *ring* when struck and those with a high-capacity sound dead and dull.

Dangler

The flexible electrode used in *barrel plating* to conduct current to the work.

Danner Process

A mechanical process for continuously drawing glass cane or tubing from a rotating mandrel.

Dark Reaction

In adhesives technology, the gelling of material in storage without light initiation.

Dark-Field Illumination

The illumination of an object such that it appears bright and the surrounding field dark. This results from illuminating the object with rays of sufficient obliquity so that none can enter the objective directly. In electron microscopy, the image is formed using only electrons scattered by the object. This is in contrast with *bright field illumination*.

Dashpot

A device used in hydraulic systems for damping down vibration. It consists of a piston attached to the part to be damped and fitted into a vessel containing fluid or air. It absorbs shocks by reducing the rate of change in the momentum of moving parts of machinery.

Daubing

In foundry practice, filling of cracks in molds or cores by specially prepared pastes or coatings to prevent penetration of metal into these cracks during pouring.

Daylight

The distance in the open position, between the moving and the fixed tables or the platens of a hydraulic press. In the case of a multiplaten press, daylight is the distance between adjacent platens. Daylight provides space for removal of the molded/formed part from the mold/die.

DBTT

Ductile/brittle transition temperature. See *impact test*.

DC Casting

This is the same as *direct chill casting*.

D

DC Direct

Direct (electric) current.

DC Intermittent Noncapacitive Arc

A low-voltage electric discharge used in spectrochemical analysis to vaporize the sample material. Each current pulse has the same polarity as the previous one and last for less than 0.1 s. See also *AC noncapacitive arc*.

DC Plasma Excitation

See *plasma jet excitation*.

DCPD

Direct current potential drop. A technique for measuring crack propagation. See *potential drop*.

Deactivation

The process of prior removal of the active corrosive constituents, usually oxygen, from a corrosive liquid by controlled corrosion of expendable metal or by other chemical means, thereby making the liquid less corrosive.

Dead Center

(1) A stationary center to hold rotating work. (2) Either of the two points in the path of a moving crank or connecting rod that lies at the ends of its stroke.

Dead Roast

A roasting process for complete elimination of sulfur. Also known as *sweet roast*.

Dead Soft

A *temper* of nonferrous alloys and some ferrous alloys corresponding to the condition of minimum hardness and tensile strength produced by *full annealing*.

Dead Time

The total time during which a spectrometer is processing information and is unavailable to accept input data.

Dead-Burned

The term applied to ceramic materials that have been fired to a temperature sufficiently high to render them relatively resistant to moisture and contraction.

Dealloying

The selective corrosion of one or more components of a solid solution alloy. This is also called parting or *selective leaching*. See also *decarburation*, *decobaltification*, *denickelification*, *dezincification*, and *graphitic corrosion*.

Dealuminification

A form of corrosion affecting aluminum bronzes, in which the aluminum is selectively removed leaving a weak, porous, copper-rich material. Similar to *dezincification of brass*.

Debond

In composites, a deliberate separation of a bonded joint or interface, usually for repair or rework purposes. Also, an unbonded or nonadherent region; a separation at the fiber–matrix interface due to strain and compatibility. In the United Kingdom, the term often refers to accidental damage. See also *disbond* and *delamination*.

Debossed

An indented or depressed design or lettering that is molded into a plastic article so that it is below the main outside surface of that article.

Debris

See *wear debris*.

Debulking

Compacting of a thick composite laminate under moderate heat and pressure and/or vacuum to remove most of the air, to ensure seating on the tool, and to prevent wrinkles.

Deburring

Removing bars, or sharp edges, or fins from metal parts by filing, grinding, or rolling the work in a barrel containing abrasives suspended in a suitable liquid medium. Sometimes called *barring*.

Debye Ring

A continuous circle, concentric about the undeviated beam, produced by monochromatic x-ray diffraction from a randomly oriented crystalline powder. An analogous effect is obtained using electron diffraction.

Debye–Scherrer Method

A method of x-ray diffraction using monochromatic radiation and a polycrystalline specimen mounted on the axis of a cylindrical strip of film. See also *powder method*.

Decalescence

A phenomenon, associated with the transformation of alpha iron to gamma iron on the heating (super heating) of iron or steel, revealed by the darkening of the metal surface owing to the sudden decrease in temperature caused by the fast absorption of the latent heat of transformation. This is in contrast with *recalcescence*.

Decarburization

Loss of carbon from the surface layer of a carbon-containing alloy due to reaction with one or more chemical substances in a medium that contacts a surface. It occurs by diffusion into, or reaction with, the environment. It is usually undesirable except in the case of certain treatments of cast iron. See also *dealloying*.

Decay Constant (λ)

The constant and the radioactive decay law $dN = -\lambda N dt$, where N is the number of radioactive nuclei present at time t . The decay constant is related to the half-life $t_{1/2}$ by the expression $t_{1/2} = \ln 2/\lambda$. See also *half-life*.

Deceleration Period

In cavitation or impingement erosion, the stage following the *acceleration period* or the *maximum rate period* (if any), during which the erosion rate has an overall decreasing trend although fluctuations may be superimposed on it.

Decibel (dB)

Unit that expresses differences of power level. Example: The decibel is 10 times the common logarithm of the power ratio. It is used to express power gain in amplifiers or power loss in passive circuits or cables.

Deckle Rod

In forming plastics, a small ride, or similar device, inserted at each end of the extrusion coating die that is used to adjust the length of the die opening.

Decobaltification

Corrosion in which cobalt is selectively leached from cobalt-based alloys, such as Stellite, or from cemented carbides. See also *dealloying* and *selective leaching*.

Decohesive Rupture

A *brittle fracture* that exhibits little or no bulk plastic deformation and does not occur by dimple rupture, cleavage, or fatigue. This type of fracture is generally the result of a reactive environment or unique microstructure and is associated almost exclusively with rupture along grain boundaries.

Decomposition

Separation of a compound into its chemical elements or components.

Decomposition Potential (or Voltage)

The *potential* of a metal surface necessary to decompose the electrolyte of a cell or a compound thereof.

Decoration (of Dislocations)

Segregation of solute atoms to the line of a dislocation in a crystal. In ferrite, the dislocations may be decorated with carbon or nitrogen atoms.

Deep Etching

In metallography, *macroetching*, especially for steels, to determine the overall character of the material, that is, the presence of imperfections, such as seams, forging bursts, shrinkage-void remnants, cracks, and coring.

Deep Groundbed

One or more *anodes* installed vertically at a nominal depth of 1.5 m (50 ft) or more below the earth's surface in a drilled hole for the purpose of supplying *cathodic protection* for an underground or submerged metallic structure. See also *groundbed*.

Deep-Draw Mold (Plastics)

A mold having a core that is appreciably longer than the wall thickness.

Deep-Drawing

Forming deeply recessed parts by forcing sheet metal to undergo plastic flow between dies, usually without substantial thinning of the sheet. Pressing operations producing cups or similar shapes having a large cup depth relative to the diameter.

Defect

(1) A discontinuity whose size, shape, orientation, or location makes it detrimental to the useful service of the part in which it occurs. (2) A discontinuity or discontinuities that by nature or accumulated effect (e.g., total crack length) render a part or product unable to meet minimum applicable acceptance standards or specifications. (3) Any deviation from perfection. This term designates rejectability. See also *discontinuity* and *flaw*.

Defect Lattice

A crystal lattice in which vacant sites act in effect as foreign atoms and hence significantly influence the material properties and characteristics.

Defective

A quality control term, describing a unit of product or service containing at least one *defect*, or having several lesser imperfections that, in combination, cause the unit not to fulfill its anticipated function. The term defective is not synonymous with nonconforming (or rejectable) and should be applied only to those units incapable of performing their anticipated functions.

Defective Weld

A weld containing one or more defects.

Define (X-Rays)

To limit a beam of x-rays by passage through apertures to obtain a parallel, divergent, or convergent beam.

D

Deflagration

Rapid combustion with noise and flames.

Deflashing

A finishing technique used to remove the flash (excess, unwanted material) on a plastic molding.

Deflection

In metal forming and forging, the amount of deviation from a straight line or plane when a force is applied to a press member. Generally used to specify the allowable bending of the bed, slide, or frame at rated capacity with a load of predetermined distribution.

Deflection Temperature under Load (DTUL)

In testing of plastics, the temperature at which a simple cantilever beam deflects a given amount under load. Formerly called heat distortion temperature.

Deflocculant

An electrolyte adsorbed on colloidal particles in suspension that charges the particles to create repulsion forces that maintain the particles in a dispersed state, thus reducing the viscosity of the suspension.

Deformability

See *conformability*.

Deformation

A change in the form of a body due to stress, thermal change, change in moisture, or other causes. Measured in units of length.

Deformation Bands

Parts of a crystal that have rotated differently during deformation to produce bands of varied orientation without individual grains. This is the same as the *Lüders lines*.

Deformation Curve

See *stress-strain curve*.

Deformation Limit

In *drawing*, the limit of deformation is reached when the load required to deform the flange becomes greater than the load-carrying capacity of the cup wall. The deformation limit (limiting drawing ratio) is defined as the ratio of the maximum blank diameter, which can be drawn into a cup without failure, to the diameter of the punch.

Deformation Point

The temperature observed during the measurement of expansivity of glass by the interferometer method at which viscous flow exactly

counteracts thermal expansion. The deformation point generally corresponds to a viscosity in the range of 1010–1011 Pa s.

Deformation Twins

This is the same as *mechanical twins*.

Deformation under Load

The dimensional change of a material under load for a specified time following the instantaneous elastic deformation caused by the initial application of the load. See also *cold flow* and *creep*.

Deformation Wear

Sliding wear involving plastic deformation of the wearing surface. Many forms of wear involve plastic deformation, so this term is imprecise and should not be used.

Degasification

See *degassing*.

Degasifier

A substance that can be added to molten metal to remove soluble gases that might otherwise be occluded or entrapped in the metal drawing solidification.

Degassing

Any process for removing gas from a solid or liquid. Heating allows hydrogen to diffuse from solid metals. Liquid metals may be degassed by, for example, adding powder to act as deoxidants or by bubbling through another gas that chemically reacts with or physically scavenges the unwanted gas.

Degassing (Metals)

(1) A chemical reaction resulting from a compound added to molten metal to remove gases from the metal. Inert gases are often used in this operation. (2) A fluxing procedure used for aluminum alloys in which nitrogen, chlorine, chlorine and nitrogen, and chlorine and argon are bubbled up through the metal to remove dissolved hydrogen gases and oxides from the alloy. See also *flux*.

Degassing (Plastics)

Opening and closing of a plastic mold to allow gases to escape during molding.

Degaussing

The elimination of all magnetic fields either by demagnetizing the material or by superimposing another field.

Degradable Plastics

Plastics that are decomposed by any of the three mechanisms—biodegradation, solubility, and photodegradation. *Biodegradable plastics* are those that are susceptible to being assimilated by

microorganisms, such as fungi and bacteria, through enzyme action. The assimilating action requires heat, oxygen, and moisture. For all practical purposes, almost all synthetic polymers are immune to enzyme attack. Only *aliphatic polyesters* and *urethanes* derived from *aliphatic ester diols*, and low-molecular-weight (under 500) unbranched *polyethylene* derivatives can be assimilated.

Biodegradable packaging resins include cellulose acetate, caprolactones, polyesters, and polylactic acids (PLAs). Bionolle aliphatic polyester is considered superior to the other resins in biodegradability.

Aliphatic polyester works in polyethylene, polypropylene, polystyrene extruded, and blown film and foam for uses such as trash bags, beverage and cosmetic bottles, and diapers. *Green Block*, from JSP Corp. of Japan, is for foam applications. PLA products include shrink film, agricultural film, compost bags, and aluminum-laminated pharmaceutical packaging, which last because PLA does not readily absorb aromatic compounds contained in pharmaceuticals, thus precluding delamination. Polyester amide, from Germany's Bayer AG, is a candidate for garbage bags, disposable flowerpots, and mulch sheet. BASF (Badische Anilin – und Soda-Fabrik) of Germany offers a starch-based thermoplastic for household and packaging film. PHB, from Germany's PCD Polymere, retains flexibility at subzero temperatures.

The solubility of *water-soluble plastics* varies with formulations, molecular weight, and temperature. *Hydroxypropyl cellulose* is soluble in water above 115°F (46°C). Below this temperature, when immersed in water, it quickly forms a slippery gel on the outer surface. The gel layer must dissolve and wash away before further dissolving takes place. *Polyethylene oxides* are soluble in water above 150°F (66°C). They are nontoxic, eatable but nonnutritive, and nonchloric, and they wash through plumbing without damage or clogging. They are resistant to grease, oil, and petroleum hydrocarbons.

Photodegradable plastics are sensitive to ultraviolet light. Energy in the form of photons breaks down the bonds between the carbon and hydrogen atoms, and oxygen-reactive free radicals are formed. The free radicals react with oxygen in the environment to produce peroxide and hydroperoxides that decompose further to produce carbonyl groups, hydroxyl groups, water, and carbon dioxide. The best photodegradable materials are the linear, nonaromatic, molecular structured plastics. Unvulcanized syndiotactic polybutadiene is typical.

Degradation

A deleterious change in the chemical structure, physical properties, or appearance of a material.

Degrease

To remove oil and grease from *adherend* surfaces.

Degreasing

Removing oil or grease from a surface. See also *vapor degreasing*.

Degree of Polymerization

Number of structural units, or mers, in the average polymer molecule in a sample measure of molecular weight.

Degree of Saturation

The ratio of the weight of water vapor associated with a pound of dry air to the weight of water vapor associated with a pound of dry air saturated at the same temperature.

Degrees of Freedom

In metallography, the number of independent variables, such as temperature, pressure, or concentration, within the phases present that may be adjusted independently without causing a phase change in an alloy system at equilibrium.

Dehydration

The loss of water by processes such as natural evaporation or heating.

Deionized Water

Water that has been passed through columns of anion and cation ion-exchange resins to remove ionic contaminants. Such water will have low conductivity but may contain nonionic material such as air, sand, or bacteria.

Delamination

The separation of layers and a laminate because of failure of the adhesive, either in the adhesive itself or at the interface between the adhesive and the adherend.

Delamination Wear

A wear process in which thin layers of material are formed and removed from the wear surface.

Delayed Elasticity

This is the same as *elastic after effect*.

Delayed Field

(1) A phenomenon involving a delay in time between the application of a stress and the occurrence of the corresponding yield-point strain. (2) The period of a few milliseconds between the rapid imposition of a load exceeding yield and the onset of yielding. It is a result of the time taken for dislocations to disengage from lattice defects such as interstitials.

Delayed Fracture

The fracture, after a significant period of time, of a component subject to a bulk stress less than its tensile strength. The stress may be residual or externally imposed. The usual cause is hydrogen embrittlement.

Deliquescence

The absorption of atmospheric water vapor by a crystalline solid until the crystal eventually dissolves into a saturated solution.

Delta Ferrite

See *ferrite*.

Delta Iron

Solid phase of pure iron that is stable from 1400°C to 1539°C (2550°F–2800°F) and possesses the body-centered cubic lattice.

D

Demarest Process

A fluid forming process in which cylindrical and conical sheet metal parts are formed by a modified rubber bulging punch. The punch, equipped with a hydraulic cell, is placed inside the workpiece, which in turn is placed inside the die. Hydraulic pressure expands the punch.

Demixing

(1) The undesirable separation of one or more constituents of a powder mixture. (2) Segregation due to over mixing.

Dendrimers

Dendritic polymers, or dendrimers, consist of highly branched globular molecules grown from a core molecule and formed in stages, allowing the molecules to be built with specific diameters, weights, and surface characteristics for improved processability. *Paman*, for example, begins with ammonia molecule, which is reacted with methylacrylate and ethylenediamine. This results in a molecule with three branches, each ending in an amino group. As the process repeats, the dendrimer grows in layers, with each amino group reacting with two ethylenediamine molecules so that the new molecule has six branches ending in an amino group. Each successive reaction doubles the number of branches. The molecular weight of Paman varies only by as little as 0.005% and contrasts with as much as 5% for straight-chain polymers.

Dendrite

(1) A crystal that has a treelike branching pattern, being most evident in cast metals slowly cooled through the solidification range. (2) The pattern of growth adopted by a crystal during solidification; it involves the progressive outward growth, in three dimensions, of solidifying branches and multiple subbranches until the solid crystal is complete.

Dendritic Powder

Particles usually of electrolytic origin typically having the appearance of a pine tree.

Dendritic Segregation

Inhomogeneous distribution of alloying elements through the arms of dendrites.

Denickelification

Corrosion in which nickel is selectively leached from nickel-containing alloys. It is most commonly observed in copper–nickel alloys after extended service and freshwater. See also *dealloying* and *selective leaching*.

Denier

A yarn and filament numbering system in which the yarn number is numerically equal to the weight in grams of 9000 m (1 denier = 1.111×10^{-7} kg/m). Used for continuous filaments. The lower the denier, the finer the yarn.

Densification

Various techniques for increasing the density of porous materials including compression and sintering.

Density Ratio

The ratio of the determined density of a powder compact to the absolute density of metal of the same composition, usually expressed as a percentage. Also referred to as percent theoretical density.

Density, Absolute

The mass per unit volume of a solid material, expressed in g/cm³, kg/m³, or lb/ft³.

Density, Dry

In powder metallurgy, the mass per unit volume of an unimpregnated sintered part.

Density, Wet

In powder metallurgy, the mass per unit volume of a sintered part impregnated with oil or other nonmetallic material.

Dental Materials

The field of dental materials is an interdisciplinary area that applies biology, chemistry, and physics to the development, understanding, and evaluation of materials used in the practice of dentistry. It is principally involved in restorative dentistry, prosthodontics, pedodontics, and orthodontics and, to a smaller extent, in the other areas of practice. The field of dental materials has advanced rapidly with the application of technologies such as genetic engineering of filling materials, computer designing and machining of restorations, adhesive bonding to teeth, dental implants, and new types of restorative materials.

Restorative Materials

The restoration of missing tooth structure is one of the most challenging areas for the use of dental materials. The enamel that covers the crown of the tooth is the hardest substance in the human body and is very resistant to physical and chemical attack. Direct restorations are put in place and hardened by a setting reaction, but require a replica of the tooth, which has to be fabricated.

Gold

Pure gold or gold foil has long been used as a restorative material. Pellets of pure gold are formed from very thin gold sheets or foils. The goal is compacted with compressed air or manually, and contoured and polished to the desired shape. These restorations are long-lasting and biologically inert. They are placed in low-stress areas because gold is soft.

Amalgam

Dental amalgam is the most frequently used direct restorative material for posterior (molar and premolar) teeth. It is formed by mixing mercury with an alloy powder of silver, tin, and copper. After mixing, there is time to insert and shape the material before it hardens.

Ag–Cu compounds and elements such as indium improve the alloy. Its advantages are ease of application, durability, and low cost; the disadvantages are chiefly aesthetic.

Resins

Composite resins are tooth-colored filling materials that were first developed for restoring anterior teeth (incisors and canines) but have found increased use as an attractive alternative to dental amalgam in posterior teeth. A composite resin consists of an organic polymer matrix reinforced with up to 80% of an inorganic filler such as SiO_2 or glass. Composite resin from a single paste is placed on the tooth and then polymerized with the help of a fiber-optic visible light source. This allows more time for contouring and gives a restoration with improved color stability. Composite resin restorations are strengthened by etching the enamel with 37% orthophosphoric acid prior to the placement of the resin to create a strong attachment to the enamel.

Glass ionomer

The only dental restorative material that forms a durable chemical bond to dentin is formed by the reaction of aluminosilicate glass with polyacrylic acid. Glass ionomer is particularly useful for restoring eroded or carious areas on exposed root surfaces with little or no enamel for bonding with composite resin. This material slowly releases fluoride to provide some additional protection from new decay. It is brittle and not used in areas of heavy stress.

Metal Castings

Crowns and inlays are made of metal castings and used when there is insufficient tooth structure to support filling. A negative of the tooth is prepared with synthetic rubber or agar, into which high-strength gypsum (plaster) is poured. This forms the replica of the tooth, to which wax is applied. An indirect lost wax process is used in fabricating dental castings. Alloy ingots used for the castings cover a range of compositions from 80% of noble metals—gold and the platinum group—combined with copper and other minor elements to base metal alloys of chromium, cobalt, and nickel. Traditionally, only noble alloys were used, but as the cost of gold increased, other alloys were developed.

Porcelain

Porcelain jacket crowns and metal crowns to which porcelain is bonded are used in visible areas. In one type, an inner core of high-strength aluminous (40%–50% Al_2O_3) porcelain is covered by feldspathic porcelain. The latter is applied to a refractory gypsum model covered with platinum foil and sintered under a vacuum at a high temperature. The porcelain powder contains metal oxides to color the crown. The other type is made from a glass ceramic of SiO_2 that is cast by the lost-wax process. After casting and contouring, the crown is heat treated to form an opaque crystal material, mica. Finally, color is applied by firing oxide stains on the surface. Porcelain and cast ceramics are used for a cosmetic veneer of the front surface of anterior teeth. The thin veneers are bonded to etched enamel with a composite resin cement. The third type of crown has a cast metal substructure for strength, onto which feldspathic porcelain is bonded by the same process described earlier.

Provisional Restoration

For provisional restorations, different materials are frequently used. While a permanent crown is being fabricated, a temporary or provisional crown protects the tooth. For best appearance, a

custom-formed poly(methyl methacrylate) or polycarbonate crown is lined with acrylic resin; aluminum crowns lined with acrylic resin can be used with posterior teeth along with the temporary crowns. These crowns are easily removed, because the cement is used that sets when paste contains the active ingredients Zn_2O and eugenol that are combined. A Zn_2O –eugenol cement reinforced with poly(methyl methacrylate) beads is also used as a temporary direct filling material for patients with deep decay.

Prosthodontic Dental Materials

The materials used with fixed prosthodontics are similar to those described earlier under *metal castings* and *porcelain*.

Orthodontic Materials

The movement and stabilization of teeth can be controlled by several unique dental materials. Stainless steel alloys are commonly used for brackets and bands on teeth, but plastic brackets are also being used to improve appearance. Brackets are bonded to etched enamel with the help of composite resin without inorganic filler. Bands encircling posterior teeth are made of stainless steel and are generally secured with a cement formed by combining Zn_2O and HPO_4 . Wires in different configurations are adapted to the dental arch to create the desired static forces for controlled tooth movement. The wires are commonly formed from wrought stainless steel, but alloys of Ni–Ti, Ti–Mo, and Co–Cr–Ni are also used.

Denudation

Local depletion of some element particularly when precipitates are formed.

Deoxidation

Removal of excess oxygen from the molten metal, usually accomplished by adding materials with a high affinity for oxygen and the removal of undesirable oxygen during melting and casting.

Deoxidation Products

Those nonmetallic inclusions that form as a result of adding the oxidizing agents to molten metal.

Deoxidized Copper

Copper from which cuprous oxide has been removed by adding a *deoxidizer*, such as phosphorous, to the molten bath.

Deoxidizer

A material that when added to molten metal combines referentially with dissolved or combined oxygen and, usually, forms a compound that becomes part of the slag.

Deoxidizing

(1) The removal of oxygen from molten metals through the use of a suitable *deoxidizer*. (2) Sometimes refers to the removal of undesirable elements other than oxygen through the introduction of elements or compounds that readily react with them. (3) In metal

D

finishing, the removal of oxide films from metal surfaces by chemical or electrochemical reaction.

Dephosphorization

The elimination of phosphorus from molten steel.

Depletion

(1) Selective removal of one component of an alloy, usually from the surface or preferentially from grain-boundary regions. (2) Reduction, particularly locally, of the quantity of alloying element. The term is used in various contexts and may indicate the loss of an element by diffusion through the matrix over significant distances (on a microscopical scale), or it may refer to localized diffusion, leading to precipitation of alloying rich precipitates. The surrounding material is then left depleted of the alloy element. See also *dealloying*.

Depolarization

A decrease in the *polarization* of an electrode.

Depolarizer

A substance that produces *depolarization*.

Deposit (Thermal Spraying)

See preferred term *spray deposit*.

Deposit Attack

Corrosion occurring beneath localized deposits, debris, etc. The deposit itself is inert but the area beneath it is low in oxygen relative to the surrounding surface and hence is relatively anodic. The metal surface beneath the deposit suffers electrolytic corrosion, and since the anode is small and the cathode large, penetration can be rapid. It is a form of *differential aeration corrosion*. See *deposit corrosion*.

Deposit Corrosion

Corrosion occurring under or around a discontinuous deposit on a metallic surface. It is also called *poultice corrosion*.

Deposit Sequence

See the preferred term *deposition sequence*.

Deposited Metal

Filler metal that has been added during a welding operation. Filler metal as opposed to fused parent metal.

Deposition

The process of applying a material to a base by means of vacuum, electrical, chemical, screening, or vapor methods, often with the assistance of a temperature and pressure container.

Deposition Efficiency (Arc Welding)

The ratio of the weight of deposited metal to the net weight of filler metal consumed, exclusive of stubs.

Deposition Efficiency (Thermal Spraying)

The ratio, usually expressed in percent, of the weight of spray deposit to the weight of material sprayed.

Deposition Rate (Thermal Spraying)

The weight of material deposited in a unit of time. It is usually expressed as kilograms per hour (kg/h) or pounds per hour (lb/h).

Deposition Sequence

The order in which the increments of weld metal are deposited. See also *longitudinal sequence*, *buildup sequence*, and *pass sequence*.

Depth Dose

The variation of absorbed dose with distance from the incident surface of a material exposed to radiation. Depth dose profiles give information about the distribution of absorbed energy in a specific material.

Depth of Cut

The thickness of material removed from a workpiece in a single machining part.

Depth of Field

The depth in the subject over which features can be seen to be acceptably in focus in the final image produced by a microscope.

Depth of Fusion/Fusion Penetration (of Weld)

The depth to which the parent material has fused, measured perpendicularly from the original surface. In the case of resistance welds, it is the maximum perpendicular distance from the original interface to the boundary of the nugget.

Depth of Penetration (Materials Characterization)

In various analytical techniques, the distance the probing radiation penetrates beneath the surface of a sample. See also *excitation volume*.

Depth of Penetration (Welding)

See *joint penetration* and *root penetration*.

Derby

A massive piece (intermediate in size, extending to more than 45 kg, or 100 lb, and usually cylindrical) of primary metal made by bomb reduction (such as uranium from uranium tetrafluoride reduced with magnesium). Compare with *biscuit* and *dingot*.

Descaling

(1) Removing the thick layer of oxides formed on some metals at elevated temperatures. (2) A chemical or mechanical process for removing scale or investment material from castings.

Deseaming

Analogous to *chipping*, the surface imperfections being removed by gas cutting.

Desiccant

A substance that can be used to dry materials because of its affinity for water and extract water or moisture from its environment.

Design Allowables

Statistically defined (by a test program) material property allowable strengths, usually referring to stress or strain. See also *A-basis*, *B-basis*, *S-basis*, and *typical basis*.

Desizing

The process of eliminating sizing, which is generally starch, from gray (also *greige*) goods before applying special finishes or bleaches (for yarn such as glass or cotton). Also, removing lubricant *size* following the weaving of a cloth.

Desorption

A process in which an absorbed material is released from another material. See also *absorption*, *adsorption*, and *chemisorption*.

Destannification

Corrosion in which tin is selectively removed from tin bronzes leaving a weak porous material. See *dezincification*, a similar but more extensively researched mechanism.

Destaticization

A treatment of plastic materials that minimizes the effects of static electricity on the surface either by treating the surface with specific materials or by incorporating materials in the molding compound. Minimization of surface static electricity prevents dust and dirt from being attracted to and/or clinging to the surface of the article.

Desulfurizing

The removal of sulfur from molten metal by reaction with a suitable slag or by the addition of suitable compounds.

Detection Limit

In an analytical method, the lowest massive concentration of an analyte that can be measured.

Detector, X-Ray

Sensor array used to measure the x-ray intensity. Typical detectors are high-pressure gas ionization, scintillator–photodiode detector arrays, and scintillator–photomultiplier tubes.

Detergent Additive

In lubrication technology, a surface-active additive that helps to keep solid particles suspended in an oil.

Detergent Oil

A heavy-duty oil containing a detergent additive. Detergent oils are used mainly in combustion engines.

Detergents

Materials that have a cleansing action like soap. Although soap itself is a detergent, as are the sodium silicates and the phosphates, the term usually applies to these synthetic chemicals, often referred to as *detergent soaps* or *soapless soaps*, which give this action. The targets may be the simple sulfonated fatty acids such as turkey-red oil, the *monopole soaps*, or highly sulfonated fatty acids or the *gardinols*, which are sulfonated fatty alcohols.

All the synthetic detergents are *surface-active agents*, or *surfactants*, with unsymmetric molecules that concentrate and orient at the interface of the solution to lower interfacial tension. They may be *anion-active agents*, with a positive-active ion; *cation-active agents*, with a negative-active ion; or *nonionic agents*. The anions and cations are sometimes called *gengenions*. Most of the household detergents are anion active and are powders. Most of the nonionics are liquids and are useful in textile processing since they minimize the difference in die affinity of various fibers. The cationics have lower detergency power and are usually skin irritants, but they have disinfectant properties and are used in washing machines and dairy cleansers. They are called *invert soaps* by the Germans. The synthetic detergents do not break down in the presence of acids or alkalies, and they do not form sludge and scum or precipitate salts in hard waters as soap does. They do not form quantities of suds as some soaps do, but suds contribute little to cleansing and are not desirable in automatic washing equipment. *Textile softeners* are different from surface-active agents. They are chemicals that attach themselves molecularly to the fibers, the polar, or charged and, of the cation orienting toward the fiber, with the fatty tails exposed to give the softness to the fabric.

Synthetic detergents have now largely replaced soaps for industrial uses. They are employed in textile washing, metal degreasing, paper-pulp processing, and industrial cleansing. They are also used in household cleansers, soapless shampoos, and toothpastes. *Biodegradable detergents* are those that can be chemically disintegrated by bacteria so that the discharge wastes do not contaminate the groundwaters. *Millox* is a group of biodegradable detergents made by the reaction of sucrose and fatty acids with a linking of ethylene oxide. This type of detergent is more powerful than petroleum-based detergents.

The detergents are more efficient than toilet soaps, but tend to leave the skin with an alkaline hardness. Lecithin may be used in detergent bars to reduce tackiness, and starch may be used for hardening.

To reduce package size, laundry detergents have become increasingly concentrated. *Phosphates*, once widely used, have lost favor because the water discharges can be environmentally damaging. *Aluminum silicate zeolites* are preferred but require additives for alkalinity, water softening, and equivalent cleaning. Containing water, however, they limit detergent concentration, and although they are effective and removing calcium, they only remove some of the magnesium, another hard water constituent.

Determination

The ascertainment of the quantity or concentration of a specific substance and a sample. See also *analysis*.

D

Detonation Flame Spraying

A thermal spraying process variation in which the controlled explosion of a mixture of fuel gas, oxygen, and powdered coating material is utilized to melt and propel the material to the workpiece.

Detritus

See *wear debris*.

Deuterium

An isotope of hydrogen. See *atomic structure*

Deuteron

The nucleus of the atom of heavy hydrogen, deuterium. The deuteron is composed of a proton and a neutron; it is the simplest multi-nucleon nucleus. Deuterons are used as projectiles in many nuclear bombardment experiments. See also *neutron* and *proton*.

Developed Blank

A sheet metal blank that yields a finished part without trimming or with the least amount of trimming.

Developer

See *dye penetrant examination*.

Deviation, X-Ray

The angle between the diffracted beam and the transmitted incident beam. It is equal to twice the Bragg angle θ .

Devitrification

(1) Crystallization in a glass. (2) The formation of crystals (seeds) in a glass melt, usually occurring when the melt is too cold. These crystals can appear as defects and glass fibers.

Devitrify

(1) To convert, partially or completely, from a glassy to a crystalline state, usually by controlled heating. (2) To deprive of glassy luster and transparency or to change from a vitreous to a crystalline condition.

Dewar flask

A vessel having double walls, the space between being evacuated to prevent the transfer of heat and the surfaces facing the vacuum being heat reflective, used to hold liquid gases and to study low-temperature phenomena.

Dewaxing

In casting, the process of removing the expendable wax pattern from an investment mold or shell mold, usually accomplished by melting out the application of heat or dissolving the wax with an appropriate solvent.

Dewetting

(1) The development and formation of a nonwetting condition after wetting has already commenced. (2) A condition that results when molten solder has coated a surface and then receded leaving irregularly shaped mounds of solder separated by areas covered with a thin solder film. The basis metal is not exposed, however.

Dewpoint Analyzer

An atmosphere monitoring device that measures the partial pressure of water vapor in an atmosphere.

Dewpoint Temperature

The temperature at which condensation of water vapor in a space begins for a given state of humidity and pressure as the vapor temperature is reduced; the temperature corresponding to saturation (100% relative humidity) for a given absolute humidity at constant pressure.

Dextrin

Also called *amylin*. A group of compounds with the same empirical formula as starch ($C_6H_{10}O_5$)_x, but with a smaller value of *x*. The compounds of stronger adhesive properties and used as pastes, particularly for envelopes, gummed paper, and postage stamps; for blending with gum arabic; in pyrotechnic compositions; and in textile finishing. Dextrin is a white, amorphous, odorless powder with a sweetish taste. It dissolves in water to form a syrupy liquid and is distinguished from starch by giving violet and red colors with iodine. Dextrin is made by moistening starch with a mixture of dilute nitric and hydrochloric acids and then exposing to a temperature of 212°F–257°F (100°C–125°C). Dextrin varies in grade chiefly owing to differences in the type of starch from which it is made. *British gum* is a name given to dextrans that give a high tack for paste use and are products containing partially converted starch.

Dezincification

A form of corrosion in warm moist environments affecting brass (copper–zinc alloys), which selectively removes the zinc, leaving weak, porous, redeposited copper of similar dimensions to the original. Localized, deeply penetrating attack is termed plug dezincification; more general surface attack is termed layer dezincification. Brass with less than about 15% zinc is not significantly affected and arsenic additions (0.02%–0.05%) inhibit attack in the higher-zinc-content, single-phase, alpha brasses, (up to 37% zinc). The alpha–beta duplex brasses can be made more resistant, but not immune, by the addition of tin, typically 1%, and arsenic up to 0.2%. The resistance of hot-worked, duplex alloys is improved by annealing at 525°C followed by water quenching. Cathodic protection can be effective. See also *dealloying* and *selective leaching*.

D-glass

A high-boron-content glass made especially for laminates requiring a precisely controlled dielectric constant.

Dilube

The removal of a lubricant from a powder compact, usually by burn-out or alternatively by treatment with a chemical solvent.

Diadic Polyamide

Polyamide produced by condensation of diamine and a dicarboxylic acid.

Diamagnetic Material

A material whose specific permeability is less than unity and is therefore repelled weakly by a magnet. Compare with *ferromagnetic material* and *paramagnetic material*.

Diametrical Strength

A property that is calculated from the load required to crush a cylindrical sintered test specimen in the direction perpendicular to the axis. See also *radial crushing strength*.

Diamond

Diamond is a highly transparent and exceedingly hard crystalline stone of almost pure carbon. When pure, it is colorless, but it often shows tints of white, gray, blue, yellow, or green. It is the hardest known substance and is placed as 10 on the Mohs hardness scale. But the Mohs scale is only an approximation, and the hardness of the diamond ranges from 5500 to 7000 on the Knoop scale, compared with 2670 to 2940 for B_4C , which is designated as 9 on the Mohs scale. The diamond always occurs in crystals in the cubical system and has a specific gravity of 3.521 and a refractive index of 2.417.

In addition, diamonds are generally electrical insulators and non-magnetic. They are quite transparent to x-rays and thus make useful pressure cell windows for x-ray measurements. Nearly, all diamonds show residual stresses in polarized light.

The melting point of diamond is given in terms of temperature and pressure because the phase diagram of carbon is such that unless pressure is maintained on diamond when at a temperature greater than 4000°C, the diamond will graphitize and then vaporize.

The diamond has been valued since ancient times as a gemstone, but it is used extensively as an abrasive, for cutting tools, and dies, for drawing wire. These industrial diamonds are diamonds that are too hard or too radially grained for good jewel cutting.

Synthetic Diamonds

These diamonds are produced from graphite at pressures from 5,512 to 12,402 MPa and temperatures from 1204°C to 2427°C. A molten metal catalyst of chromium, cobalt, nickel, or other metal is used, which forms a thin film between the graphite and the growing diamond crystal. Without the catalyst, much higher pressures and temperatures are needed. The shape of the crystal is controllable by the temperature. At the lower temperatures, cubes predominate, and at the upper limits, octahedra predominate; at the lower temperatures, the diamonds tend to be black, whereas at higher temperatures, they are yellow to white. The synthetic diamonds produced by the General Electric Co. are up to 0.01 carat in size and are of industrial quality comparable with natural diamond powders.

CVD Diamonds

A newer production method uses chemical vapor deposition (CVD) to produce a sheet of diamonds consisting of countless diamonds,

each only a few micrometers across. The CVD diamonds have similar properties to those made by the older method. However, they conduct heat better than any known material—five times better than copper—making them useful as heatsinks to conduct heat away from electrical components.

The CVD process has been used to coat the cutting surfaces of tungsten carbide rotating tools such as routers, end mills, and drills. The technique should bring substantial productivity improvement to the machining of composites, carbon fiber, and glass/fiberglass-reinforced composites, epoxy resins, and graphite.

Tests show diamond-coated tools last up to 50 times longer than tungsten carbide ones and more than twice as long as polycrystalline diamond tools in aerospace applications. In addition to greater longevity, longer unattended runs, and fewer tool changes, diamond-coated tools also can run at higher speeds and feeds than conventional tools.

The CVD process allows round tools of virtually any shape or size to be diamond coated with no subsequent brazing or grinding.

Applications

Several types of grinding wheels (usually distinguished by the bond material) are made that carry diamonds as the abrasive material. Wheel bonds may be resinoid, vitrified, metal, etc. Diamond grit sizes in these wheels may vary from 0.0254 to 0.762 mm. In general, the diamond-carrying material is placed in a rather thin layer on the working surface of the wheel.

Wheel surface speeds of 22.5–33 m/s are recommended. Most grinding is done wet. By far, the greatest use for diamond wheels is in shaping and sharpening tungsten carbide tools. In addition, diamond wheels are used for edging and beveling glass and for lens grinding. Also, artificial sapphire is sliced and formed with diamond grinding wheels.

Diamond dust is a powder obtained by crushing the fragments of bort or from refuse from the cutting of gem diamonds. It is used as an abrasive for hard steels, for cutting other stones, and for making diamond wheels for grinding. Grit sizes for grinding wheels are 80–400. The coarsest, No. 80, for fast cutting, has about 1400 particles per square inch in the face of the bonded wheel.

Diamond drills range from small, diamond-tipped dental drills up to oil-well core bits containing 1000 carats. A 10.16 cm core bit may be set with 150–300 diamonds varying in size from 1/10 to 1/30 carat. As much as 3048 cm of limestone can be drilled before the diamonds require resetting in the hard metal matrix.

Diamond wire drawing dies are required for tungsten filament wire and preferred for many other wire materials. The low friction coefficient may contribute to the success of diamond in this application. Stones for wire drawing are large (up to 8 carats for 2.54 mm copper wire) and free from flaws and inclusions.

Single-point diamond lathe tools are made by setting a stone in the end of a steel shank suitable for mounting in a machine tool such as a lathe. The stone is mounted with consideration for its shape and crystallographic axis. After mounting, the tool is ground to the required shape on diamond grit wheels and polished on a scaife.

Single-point diamond tools are designed with angles between phases of 80° or greater to avoid the breakage that would occur if slender points were used. Diamond tools are not suitable for heavy cuts particularly on ferrous material. Accurate, fine finish cuts may be made on nonferrous metals and plastics. Tool wear is slow, so accuracy is maintained for many workpieces. A diamond tool maintains its cutting edge about 25 times as long as a high-speed steel tool and 3–4 times as long as a carbide tool.

D

Diamond Boring

Precision boring with a shaped diamond (but not with other tool materials).

Diamond Film

A carbon-composed film, usually deposited by chemical vapor deposition or related process, that has the following three characteristics: (1) a crystalline morphology that can be visually discerned by scanning electron or optical microscopy, (2) a single-phase crystalline structure identifiable by x-ray and/or electron diffraction, and (3) a Raman spectrum typical for crystalline diamond. See also *diamondlike film*.

Diamond Films

A new method has been developed for creating amorphous diamond films that are harder than any other coating, except for crystalline diamond. The new coatings are also smooth and can be created at room temperature, whereas crystalline diamond coatings need high temperatures and have rough surfaces.

This newly developed method uses a pulsed laser hitting a graphite target to deposit a carbon film containing a high percentage of diamondlike bonds. Heating the film illuminates internal stresses while allowing the film to retain diamondlike properties, including 90% of the stiffness and hardness of crystalline diamond. An added benefit is that researchers can control the level of stress. In fact, scientists have made stress-free films more than 7 μm thick and applied the coatings to plastic substrates as well as freestanding membranes more than an inch in diameter and less than 600 Å and tested to 800°C. Besides being incredibly hard, the films resist wear with low coefficient of friction and are almost inert to all chemicals. The films could find use as coatings for metal tools, auto parts, and biomedical devices.

Other methods have been developed that offer a lower-cost alternative by coating and chemically bonding an inexpensive substrate with a thin film of diamondlike carbon (DLC).

These diamond films have great potential as chemically inert protective coatings that make machine tools and parts last 10 times longer. Other applications include optical instruments, medical equipment, watch crystals, and eyeglasses.

This method is called direct ion-beam deposition for applying DLCs to a substrate. An ion generator creates a stream of ions from a hydrocarbon gas source; the C ions impinge directly on the target substrate and *grow* into a thin DLC film. This low-pressure, low-temperature process allows use of plastics and other substrates that cannot withstand the high pressures and temperatures normally used to synthesize diamonds.

Other commercial DLC applications include coatings for magnetic data-storage disks, surgical needles, and a diamond-coated ball for an artificial hip joint.

Diamond Pyramid Hardness Test

Hardness testing using a pyramid-shaped diamond indenter. See the *Vickers hardness test*.

Diamond Tool

(1) A diamond shape or form to the contour of a single-point cutting tool, for use in precision machining of nonferrous or nonmetallic materials. (2) An insert made from polycrystalline diamond compacts.

Diamond Wheels

A grinding wheel in which crushed and sized industrial diamonds are held in a resinoid, metal, or vitrified bond.

Diamondlike Film

A hard, noncrystalline carbon film, usually grown by chemical vapor deposition or related techniques, which contain predominantly sp^2 carbon-carbon bonds. See also *diamond film*.

Diaphragm

(1) A fixed or adjustable aperture in an optical system. Diaphragms are used to intercept scattered light, to limit field angles, or to limit image-forming bundles or rays. (2) A porous or permeable membrane separating anode and cathode compartments of an electrolytic cell from each other or from an intermediate compartment. (3) Universal die member made of rubber or similar material used to contain hydraulic fluid within the forming cavity and to transmit pressure to the part being formed.

Diaphragm Gate

A gate used in molding annular or tubular plastic articles. The gate forms a solid web across the opening of the part. This is also called *disk gate*.

Diatomaceous Earth

A class of compact, granular, or amorphous minerals composed of hydrated or *opaline silica*, used as an abrasive, for filtering, in metal polishes and soaps, as a filler in paints and molding plastics, for compacting into insulating bricks and boards, and in portland cement for fine detail work and for waterproofing. It is formed of fossil diatoms in great beds and is not earthy. In mineralogy, it is called *diatomite*.

After mining, the material is crushed and calcined. When pure, it is white; with impurities, it may be gray, brown, or greenish. The powder is marketed by fineness and chemical purity. Its high resistance to heat, chemical inertness, and dielectric strength and the good surface finish it imparts make it a desirable filler for plastics. For insulating purposes, bricks or blocks may be sawed from the solid or molded from the crushed materials, or it may be used in powder form. *Diatomite block* has a porosity of 90% of its volume and makes an excellent filter. *Celite*, of Celite Corp., is a 325-mesh, uncalcined, amorphous diatomaceous earth for portland cement mixtures and is used as a flattening agent in paints. *Sil-O-Cel* is diatomaceous earth in powder or in insulating block to withstand temperatures to 1600°F (871°C). *Compressible insulation*, to absorb the expansion stresses known as drag stress, between the firebrick and the steel shell of metallurgical furnaces, may be of diatomaceous silica. *Superex SG*, for blast furnaces, is a composite block with Superex on the hot side and a blanket of fine spun glass fibers on the cold side.

Dichromate Treatment

A chromate *conversion coating* produced on magnesium alloys and a boiling solution of sodium dichromate.

Didymium

A natural mixture of the rare earth elements praseodymium and neodymium, often given the quasi-chemical symbol Di.

Die

A tool, usually containing a cavity, that imparts shape to solid, molten, or powdered metal primarily because of the shape of the tool itself. It is used in many press operations (including blanking, drawing, forging, and forming), in die casting and in forming green powder metallurgy compacts. Die-casting and powder metallurgy dies are sometimes referred to as *molds*. See also *forging dies*.

Die

A master component that imposes its shape on another material. Manufacturing processes include drawing in which bar, tube, or wire is pulled through the die orifice. Extrusion, a process in which material is pushed through a die. Die stamping, forming, or forging in which material is pressed between shaped die faces and die casting in which molten metal is poured or injected into reusable shaped metal dies rather than into expendable sand molds.

Die Adapter

Informing plastics, the part of an extrusion die that holds the die block.

Die Assembly

The parts of a die stamp or press that hold the die and locate it for the punches.

Die Barrel

In powder metallurgy presses, a tubular liner for a die cavity.

Die Block

A block, often made of heat-treated steel, into which desired impressions are machined or sunk and from which closed-die forgings or sheet-metal stampings are produced using hammers or presses. In forging, die blocks are usually used in pairs, with part of the impression in one of the blocks and the rest of the impression in the other. In sheet-metal forming, the female die is used in conjunction with a male punch. See also *closed-die forging*.

Die Body

The stationary or fixed part of a powder pressing die.

Die Bolster

In powder metallurgy presses, the external steel ring that is shrunk fit around the hard parts comprising the die barrel.

Die Castings

Die castings are made by forcing molten metal under high pressure into a steel die containing an impression of the part to be made, which is called the die cavity. The process is most useful for the high-production manufacture of small- to medium-sized castings. Economies of the process are developed through the following:

1. *High speed of production:* The output from a die is many times more than four other casting processes.

2. *Strategic use of metal:* Through casting thinner walls, by coring holes and passages, and by contouring the die halves carefully, material can be saved and the casting made lighter.
3. *Dimensional accuracy:* The reproducibility is very good and dimensional tolerances can be held close enough to eliminate many machining operations.

Production

Die castings are made in a special machine containing a clamping mechanism to open and close the die and to hold the die halves together and an injection mechanism to force the metal into the die. Injection mechanisms can be of two types. The first system, the immersed plunger type, is suitable for alloys such as tin, lead, zinc, and sometimes magnesium where attack of the molten metal on the parts of the mechanism is insignificant. The die containing the cavity is closed and held tightly in the clamping mechanism, while the metal is injected by the downward motion of the plunger, which is operated by a hydraulic cylinder. The filling of the die is accomplished in less than 1/10 s. Dies can be opened in a few seconds, the casting removed by ejector pins, and the cycle repeated. Casting rates vary from 50/h for heavy parts to 15,000/h for small parts made on automatic machines.

Metals such as aluminum, brass, and magnesium, which because of either their solvent action or high melting temperatures are not adaptable to the immersed plunger system, can be cast by the second type, the cold chamber system, where the metal is melted in a separate unit and is hand-ladled or metered into a shot cylinder securely fastened to the die. The injection force is applied by a plunger that in turn is operated by a hydraulic cylinder. Higher pressures (200–1000 atm) are used in a cold chamber machine permitting improved density and mechanical properties of the die casting.

Characteristics

Die castings have smooth, dense surfaces, which require a minimum amount of finishing. A major advantage of die casting is the close tolerances that can be held. These substantially reduce machining operations and are largely responsible for the economy of the process.

Intricate casting shapes can be readily made through the use of cores and slides, ribs, and bosses. Special properties can be obtained by casting in inserts such as bronze sleeves, laminated pole shoes, magnets, and hardened steel plates.

One limitation of the process is the expense of the dies, which must be amortized over the expected production. However, most automotive, appliance, or business machine production is large enough that the tool and die costs become a small portion of the total casting cost and they are completely offset by manufacturing economies due to elimination of machining of parts after processing.

Average wall thickness for medium-sized parts and aluminum and magnesium is 2.2 mm and for large parts is 2.5–3.9 mm. Wall thickness for zinc will run approximately 75% of aluminum and magnesium because of the ease of casting of zinc in comparison to the light metals. Minimum wall thicknesses vary with the size of the part—1 mm is generally accepted for zinc and 1.3 mm for aluminum and magnesium.

Application

The largest single consumer of die castings is the automotive industry. Zinc is used for ornamentation and hardware such as radio grilles, instrument clusters, and housings, as well as for functional

D

parts such as carburetors, fuel pumps, and speedometer housings. Zinc is used in appliances such as washing machines, dryers, electric ranges, and refrigerators for decorative and functional parts. It is also used for camera cases and projector housings and for toys. Military uses include precision fuse parts.

Because aluminum and magnesium can be used almost interchangeably, relative cost is often the governing selection factor. Automotive uses of aluminum die castings include transmission cases, torque converter housings and extensions, valve bodies, and carburetors. In the business machine field, typewriters are the largest application for aluminum die castings. The optical industry also uses aluminum die castings for binoculars, camera cases, projector frames, and other parts. Military uses are varied and include ordinance parts such as fuses, windshields, aircraft engine accessory parts, and airframe parts, as well as some small missile airframe parts. The electrical industry uses aluminum and magnesium for instrument housings and frames and for brush holders.

Materials

Dies are generally made of alloy steels and are relatively expensive. Dies for zinc can be made from prehardened steels of the SAE 4140 type. Dies for aluminum and magnesium are made from the Cr–Mo H-11 or H-13 steels heat-treated to C46–C48 Rockwell.

Zinc castings are made from high-purity Zn–Al alloys containing 4% aluminum with or without copper and containing approximately 0.03% magnesium. Impurities such as tin, lead, and cadmium must be kept at very low values, on the order of 0.005% or less, to avoid deterioration of the alloy in humid atmospheres. Zinc alloys have high tensile strength (292.4 MPa) and high impact strength (54.2 J). These properties change with decreasing temperature so that the useful temperature range for zinc is only recommended between 0°C and 93°C.

Aluminum die-casting alloys are made from the Al–Si, Al–Si–Cu, or Al–Mg series. These alloys have the best castability of physical properties for the die-casting process. Mechanical properties will vary between 276 and 325 MPa tensile strength, 135 and 172 MPa yield strength, and 3% and 5% elongation. Die castings of aluminum have high fatigue strength (135–142 MPa), which makes them particularly adaptable to structural uses where cyclic stresses are involved.

Magnesium alloys are of the Al–Zn type having tensile strength of 234 MPa, yield strengths of 142 MPa, and an elongation of 3%.

Copper alloys used are low-melting silicon brasses with tensile strength of 345–584 MPa, yield strength of 241–345 MPa, and an elongation of 15%–25%.

Die Cavity

The machine recess that gives a forging or stamping its shape.

Die Check

A crack in a die impression due to forging and thermal strains at relatively sharp corners. Upon forging, these cracks become filled with metal, producing sharp ragged edges on the part. Usual die wear is the gradual enlarging of the die impression due to erosion of the die material, generally occurring in areas subject to repeated high pressures during forging.

Die Clearance

Clearance between a mated punch and die, commonly expressed as clearance per side. This is also called clearance or punch-to-die clearance.

Die Cushion

A press accessory placed beneath or within a bolster plate or die block to provide an additional motion or pressure for stamping or forging operations, actuated by air, oil, rubber, springs, or a combination of these.

Die Cutting

Cutting shapes from metal sheet stock by sharply striking it with a shaped knife edge known as a steel rule die. Clicking and dinking are other names for die cutting of this kind.

Die Fill

A die cavity filled with powder.

Die Forging

A forging that is formed to the required shape and size through working in machined impressions in specially prepared dies.

Die Forming

The shaping of solid or powdered metal by forcing it into or through the *die cavity*.

Die Height

In forming, the distance between the fixed platen and the moving one when dies are closed.

Die Holder

A plate or block, on which the die block is mounted, having holes or slots for fastening to the *bolster plate* or the *bed* of the press.

Die Impression

The portion of the die surface that shapes a forging or sheet metal part.

Die Insert

A relatively small die that contains part or all of the impression of a forging or sheet metal part and is fastened to the master *die block*.

Die Layout

The transfer of drawing or sketch dimensions to templates or die surfaces for use in sinking dies.

Die Life

The productive life of a *die impression*, usually expressed as the number of units produced before the impression has worn beyond permitted tolerances.

Die Lines

Lines or markings on form, drawing, or extruded metal parts caused by imperfections in the surface of the die.

Die Lubricant

(1) A lubricant applied to the working surfaces of dies and punches to facilitate drawing, pressing, stamping, and/or ejection. In powder metallurgy, the die lubricant is sometimes mixed into the powder before pressing into a compact. (2) A compound that is sprayed, swabbed, or otherwise applied on die surfaces or the workpiece during the forging or forming process to reduce friction. Lubricants also facilitate release of the part from the dies and provide thermal insulation. See also *lubricant*.

Die Match

The condition where dies, after having been set up in a press or other equipment, are in proper alignment relative to each other.

Die Opening

(1) In flash or upset welding, the distance between the electrodes, usually measured with the parts in contact before welding has commenced or immediately upon completion of the cycle but before upsetting. (2) In powder metallurgy, the entrance to the die cavity.

Die Pad

In forming, a movable plate or pad in a female die; usually used for part ejection by mechanical means, springs, or fluid cushions.

Die Plate

The base plate of a press into which the die is sunk.

Die Proof

A casting of a *die impression* made to confirm the accuracy of the impression.

Die Pull

The direction in which the solidified casting must move when it is removed from the die. The die pull direction must be selected such that all points on the surface of the casting move away from the die cavity surfaces.

Die Scalping

Removing surface layers from bar, rod, wire, or tube by drawing through a sharp-edged die to eliminate minor surface defects.

Die Separation

The space between the two halves of a die-casting die at the parting surface when the dies are close. The separation may be the result of the internal cavity pressure exceeding the locking force of the machine or warpage of the die due to thermal gradients in the die steel.

Die Set

(1) The assembly of the upper and lower die shoes (punch and die holders), usually including the *guide pins*, *guide pin bushings*, and

heel blocks. This assembly takes many forms, shapes, and sizes and is frequently purchased as a commercially available unit. (2) Two machined dies used together during the production of a *die forging*.

Die Shaft

The condition that occurs after the dies have been set up in a forging unit in which a portion of the impression of one die is not in perfect alignment with the corresponding portion of the other die. This results in a mismatch in the forging, a condition that must be held within the specified tolerance.

Die Shoes

The upper and lower plates or castings that constitute a die set (punch and die holder). Also, a plate or block upon which a *die holder* is mounted, functioning primarily as a base for the complete *die assembly*. This plate or block is bolted or clamped to the *bolster plate* or the face of the press *slide*.

Die Sinking

The machining of the die impression to produce forgings of required shapes and dimensions.

Die Space

The maximum space (volume), or any part of the maximum space, within a forming or forging press for mounting a die.

Die Stamping

The general term for a sheet metal part that is formed, shaped, or cut by a die in a press in one or more operations.

Die Steels

Any of the various types of *tool steels* used for cold- and hot-forming dies, including forging, casting, and extrusion dies, stamping and trim dies, piercing tools and punches, molds, and mandrels. In general, all the major families of tool steels except the high-speed types are used for dies, including the hot-work, cold-work, shock-resisting, mold, special-purpose, and water-hardening types. The high-speed types, however, which are typically used for cutters, are also used for punches.

Die steel is any steel capable of achieving the necessary high strength without cracking or unacceptable distortion. Hence, they are usually, high-carbon low-alloy steels with corresponding good hardenability. For hot-working application, higher levels of chromium (5% or more) or tungsten (10% or more) are common.

Die Swell Ratio

In forming plastics, the ratio of the outer parison diameter (or parison thickness) to the outer diameter of the die (or die gap). Die swell ratio is influenced by head construction, land length, extrusion speed, and temperature. See also *parison* and *parison swell*.

Die Volume

See the preferred term *fill volume*.

D

Die Welding

See the preferred terms of *forge welding* and *cold welding*.

Dielectric

A nonconductor of electricity. It is the ability of a material to resist the flow of an electric current.

Dielectric Curing

The curing of a synthetic thermosetting resin by the passage of an electric charge (produced from a high-frequency generator) through the resin.

Dielectric Heating

The heating of plastic materials by dielectric loss in a high-frequency electrostatic field.

Dielectric Loss

A loss of energy evidenced by the rise in heat of a dielectric placed in an alternating electric field. It is usually observed as a frequency-dependent conductivity.

Dielectric Materials

These are materials that are electrical insulators or in which an electric field can be sustained with a minimum dissipation of power. A solid is a dielectric if its valence band is full and is separated from the conduction band by at least 3 eV.

Dielectrics are employed as insulation for wire cables and electrical equipment, as polarizable media for capacitors, in apparatus used for the propagation or reflection of electromagnetic waves, and for a variety of artifacts, such as rectifiers and semiconductor devices, piezoelectric transducers, dielectric amplifiers, and memory elements.

The ideal dielectric material does not exhibit electrical conductivity when an electric field is applied. The term *dielectric*, although it may be used for all phases of matter, is usually applied to solids and liquids. In practice, all dielectrics have some conductivity, which generally increases with increasing temperature and applied field. For a good dielectric, such as polytetrafluoroethylene, the low-field DC conductivity at room temperature may be lower than $10^{-16} \Omega \text{ m}$, whereas the corresponding figure for some specimens of plasticized polyvinyl chloride (PVC) may be as high as $10^{-4} \Omega \text{ m}$, similar to that of the low-conductivity semiconductors.

Breakdown

If the applied field is increased to some critical magnitude, the material abruptly becomes conducting, a large current flows (often accompanied by a visible spark), and local destruction occurs to an extent dependent upon the amount of energy that the source supplies to the low-conductivity path. This critical field depends on the geometry of the specimen, the shape and material of the electrodes, the time variation of the applied field, and other factors. Temperature instability can occur because of the heat generated through conductivity or dielectric losses, causing thermal breakdown.

Industrial Dielectric Materials

Many of the traditional materials are still in common use, and they compete well in some applications with newer materials regarding

their electrical and mechanical properties, reliability, and cost. For example, oil-impregnated paper is still used for high-voltage cables; usually paper and various types of pressboard and mica, often as components of composite materials, are also in use. Elastomers and press-molded resins are also of considerable industrial significance. However, synthetic polymers such as polyethylene, polypropylene, polystyrene, polytetrafluoroethylene, PVC, polymethyl methacrylate, polyamide, and polyimide have become important, as has polycarbonate because it can be fabricated into very thin films.

Properties of Polymers

Generally, these have crystalline and amorphous regions, increasing crystallinity causing increased density, hardness, and resistance to chemical attack, but often producing brittleness. Many commercial plastics are amorphous copolymers, and often additives are incorporated in polymers to achieve certain characteristics or to improve their workability. Additives include inorganic fillers, antioxidants, stabilizers, and pigments.

Polyethylene

Polyethylene ($\text{C}_n\text{H}_{2n+2}$) is the most common and most investigated polymer. It is relatively inexpensive and is easily worked. Polyethylene readily oxidizes, and so its working temperature is normally not above 70°C ; although it may be worked at higher temperatures (e.g., up to 90°C) in suitable circumstances, it normally contains antioxidants.

Polyethylene Terephthalate

Polyethylene terephthalate is a useful material that has good resistance to acids and alkalis provided that they are diluted. It is insoluble in many common solvents, although it does dissolve in aromatic and chlorinated hydrocarbons, especially when warm. It softens above 250°C .

Polypropylene

Polypropylene is similar in structure to polyethylene, but every other carbon atom has one of the H_2 atoms replaced by a CH_2 group. Although electrically similar to polyethylene, polypropylene can be made in thinner films, say $5 \mu\text{m}$ as against about $25 \mu\text{m}$ for polyethylene. These films replace paper for impregnated capacitors, with reduced loss.

Polystyrene

Polystyrene is brittle at room temperature, becomes soft at 80°C , and is often modified by copolymerization. Traditionally, it is used in film form for capacitors, and it remains competitive for this application. Polystyrene is also used for coaxial cable insulation, but in round strip or bead form, because the solid is not very flexible.

Polytetrafluoroethylene

Polytetrafluoroethylene is similar to polyethylene, with all the H_2 atoms replaced by fluorine atoms. Highly crystalline (about 95), it resists twisting and bending and is mechanically tough, with a low coefficient of friction, 0.06. It is highly resistant to chemical attack and is useful for hostile environmental conditions.

Polyvinyl Chloride

PVC has a structure similar to that of polyethylene, but every other carbon atom has one of its H_2 atoms replaced by a chlorine atom. It is only about 10% crystalline and is compatible with a large number of other polymers. It is easily decomposed by heat and is not

suitable for continuous use at 70°C. PVC is not well characterized and, depending on admixtures, may be molded; its main electrical use is coating wires.

Polymethyl Methacrylate

Polymethyl methacrylate is a clear solid, hard but easily scratched. Its dielectric properties are only moderate, and its use is restricted to undemanding conditions at normal ambient temperatures, usually in a molded form, where appearance is important.

Polyamide

Polyamide may be in linear form, known as nylon, or in aromatic form. Neither of these is of much value as a dielectric, but nylons, because of their toughness and resistance to solvents, are used to form coatings to protect insulation. The aromatic form can also make yarns, but it is most often used in impregnated board from which it gives low-voltage insulation capable of being used continuously at temperatures of 150°C, or even higher.

Polyimide

Polyimide is related to aromatic polyamide, but with additional aromatic groups. Expensive to produce, it can be made into films down to 25 µm thick and in varnish form for wire coating. It is very tough, does not burn but chars above 800°C, and remains flexible at liquid helium temperatures; it can be used continuously up to 250°C.

Resins

The resins are important members of the family of cross-linked polymers. Epoxy resins have a high mechanical strength, absorb very little water, and bond easily to most materials but not to polyethylene. They are used for bonding and encapsulation, and their properties can be modified by the curing process used and by the use of fillers and hardeners.

Dielectric Monitoring (of Plastics)

Monitoring the cure of thermosets by tracking the changes in their electrical properties during material processing.

Dielectric Shield

In a *cathodic protection* system, an electrically nonconductive material, such as a coating, or plastic sheet, or pipe, that is placed between an anode and an adjacent cathode to avoid current wastage and to improve current distribution, usually on the cathode.

Dielectric Strength

(1) The maximum voltage that a dielectric can withstand, under specified conditions, without resulting in a voltage breakdown (usually expressed as volts per unit dimension) and (2) A measure of the ability of a dielectric (insulator) to withstand a potential difference across it without electric discharge.

Dielectrometry

Use of electrical techniques to measure the changes in loss factor (dissipation) and in capacitance during cure of the resin and a laminate. This is also called dielectric spectroscopy.

Die-Parting Line

A lengthwise flash or depression on the surface of a protruded plastic part. The line occurs where separate pieces of the die join together to form the cavity.

Differential Aeration Cell

An *electrolytic cell*, the *electromagnetic force* of which is due to a difference in air (oxygen) concentration at one electrode as compared with that at another electrode of the same material. See also *concentration cell*.

Differential Aeration Corrosion

Corrosion resulting from variations in air, more specifically oxygen content at different points on an immersed component. The electrolytic corrosion occurs at the unnoticed, low-oxygen, areas. Such attack in crevices may be termed crevice corrosion or, if beneath debris, deposit attack.

Differential Coating

A coated product having a specified coating on one surface and a significantly lighter coating on the other surface (such as a hot-dipped galvanized product or electrolytic tin plate).

Differential Flotation

Separating a complex ore into two or more valuable minerals and *gangue* by *flotation*. This is also called selective flotation.

Differential Heating

Heating that intentionally produces a temperature gradient within an object such that, after cooling, a desired stress distribution or variation in properties is present within the object.

Differential Interference Contrast Illumination

A microscopic technique using a beam-splitting double-quartz prism, that is, a modified Wollaston prism placed ahead of the objective together with a polarizer and analyzer in the 90° crossed positions. The two light beams are made to coincide at the focal plane of the objective, revealing bright differences as variations in color. The prism can be moved, shifting the interference image through the range of Newtonian colors.

Differential Scanning Calorimetry (DSC)

Measurement of energy absorbed (endotherm) for production (exotherm). This may be applied to melting, crystallization, resin curing, loss of solvents, and other processes involving an energy change. It may also be applied to processes involving a change in heat capacity, such as the glass transition.

Differential Thermal Analysis (DTA)

An experiment analysis technique in which a specimen and a control are heated simultaneously and the difference in their temperatures is monitored. The difference in temperatures provides information on relative

D

heat capacities, presence of solvents, changes in structure (i.e., phase changes, such as melting of one component in a resin system), and chemical reactions. See also *differential scanning calorimetry*.

Diffraction

(1) A modification that radiation undergoes, for example, in passing by the edge of opaque bodies or through narrow slits, in which the rays appear to be deflected. (2) Coherent scattering of x-rays by the atoms of a crystal that necessarily results in beams in characteristic directions. This is sometimes termed as reflection. (3) The scattering of electrons by any crystalline material through discrete angles depending only on the lattice spacings of the material in the velocity of the electrons.

Diffraction Contrast

In electron microscopy, contrast produced by intensity differences in Bragg diffracted beams from a crystalline material. These differences are caused by regions of varying crystal orientation.

Diffraction Grating

A series of a large number of narrow, close, equally spaced, diffracting slits or grooves capable of dispersing light into its spectrum. See also *concave grating* and *reflection grating*. Compare with *transmission grating*.

Diffraction Pattern

The spatial arrangement and relative intensities of diffracted beams.

Diffraction Ring

The diffraction pattern produced by a given set of planes from randomly oriented crystalline material. See also the *Debye ring*.

Diffuse Transmittance

In materials characterization, the transmittance value obtained when the measured radiant energy has experienced appreciable scattering in passing from the source to the receiver. See also *transmittance*.

Diffusion

(1) Spreading of a constituent in a gas, liquid, or solid, tending to make the composition of all parts uniform. (2) The spontaneous movement of atoms or molecules to new sites within a material. (3) The movement of a material, such as a gas or liquid, in the body of a plastic. If the gas or liquid is absorbed on one side of a piece of plastic and given off on the other side, the phenomenon is called permeability. Diffusion and permeability are not due to holes or pores in the plastic but are caused and control by chemical mechanisms. (4) The movement of individual atoms, ions, and molecules relative to the remainder of the material. The movement of individual atoms is random but where there is a concentration gradient in a large number of movements, there will be a net effect for atoms to move down the gradient. Ultimately, over a sufficient period of time, a uniform composition will develop. The rate of diffusion is fastest in gases and slower in fluids, but it is still significant in solid materials, and diffusion is a critical factor in many solid-state processes and phenomena. The rate of diffusion is accelerated by increasing the temperature.

Diffusion Aid

A solid filler metal sometimes used in *diffusion welding*.

Diffusion Bonding

Diffusion across the interface between solid contacting surfaces producing a bond of useful strength. Clean, close-fitting interfaces are vital. Heating is normally required as is a small amount of pressure. If the pressure is high, for example, sufficient to disrupt surface films, the joint is more correctly termed a *pressure weld*. See also *diffusion welding*, which is very similar to *diffusion brazing*.

Diffusion Brazing

A brazing process that produces coalescence of metals by heating them to suitable temperatures and by using a filler metal or an in situ liquid phase. The filler metal may be distributed by capillary action or may be placed or formed at the faying surfaces. The filler metal is diffused with the base metal to the extent that the joint properties have been changed to approach that of the base metal. Pressure may or may not be applied.

Diffusion Coating

Any process whereby a base metal or alloy is either (1) coated with another metal or alloy and heated to a sufficient temperature in a suitable environment or (2) exposed to a gaseous or liquid medium containing the other metal or alloy, thus causing *diffusion* of the coating or of the other metal or alloy into the base metal with resultant changes in the composition and properties of its surface.

Diffusion Coatings

A large number of elements can be diffused into the surface of metals to improve their hardness and resistance to wear, corrosion, and oxidation. Diffusion coatings (sometimes called cementation coatings) are applied by heating the base metal in an atmosphere of the coating material, which diffuses into the metal. The term may include sprayed or electroplated deposits that are subsequently heated to allow diffusion.

Calorized

Aluminum (calorized) coatings are applied by diffusion to carbon and alloy steels to improve their resistance to high-temperature oxidation. They can be applied by treating the metal in powdered aluminum compounds or in AlCl_3 vapor or by spraying the aluminum on and subsequently heat-treating it. The alloy coating formed (about 25% aluminum) protects the metal by stealing it from the surrounding air. The coatings range in depth from 5 to 40 mils and permit parts to remain serviceable for many years at temperatures up to 760°C. They have also been used for intermittent exposure as high as 927°C. Typical high-temperature uses are chemical and metal processing pots, bolts, air heater tubes, and parts for furnaces, steam superheaters, and oil and gas polymerizers.

Carburized

Carburizing allows steels to retain high internal strength and toughness and at the same time have high surface hardness. The hardened surface is produced by introducing carbon into a steel surface by heating the metal above the transformation temperature while it is in contact with carbonaceous material, which may be a solid, gas, or liquid.

In general, carburizing is limited to steels low enough in carbon (below about 0.45%) to take up that element readily. Plain carbon steels are generally used if surface hardness is the principal requirement and core properties are not too critical. Alloy steels must usually be used if high hardness and toughness are needed in the core. Typical applications are gears, cams, pawls, racks, and shafts.

Chromized

Chromizing is the process of diffusing chromium into ferrous metals to improve their resistance to corrosion, heat, and wear. Typical of the chromizing methods that have been developed is one in which the parts to be treated are packed in a proprietary powdered chromium compound and heated to 816°C–1038°C. This method produces high Cr–Fe alloy on ferrous metals with a low carbon content.

The case (3 mils thick) exhibits good resistance to sealing and corrosion at high temperatures. A CrC case is produced on high-carbon materials such as cast iron, iron powder, tool steel, and plain carbon steels containing over 0.40% carbon. This case (1/2–2 mils thick) has a hardness of 1600–1800 vpn.

Cyanided, Carbonitrided

Both cyaniding and carbonitriding produce a hard and wear-resistant surface on low-carbon steels. Both methods cause carbon and N₂ to diffuse into the surface of the base metal. The case developed has high hardness after quenching. The methods differ in that a liquid bath is used in cyaniding, whereas a gas atmosphere is used in carbonitriding.

In general, cyaniding and carbonitriding are used with the same base metals and for the same applications as carburizing. Warpage is usually less serious than in carburizing. Quenching is usually required for full hardness, but file hardness can be obtained without quenching.

Ni–P Coated

With some exceptions, Ni–P coatings can be roughly classified as diffusion coatings. The coatings are prepared from NiO₂ to basic NH₃PO₄ and water and are applied to ferrous surfaces just like a paint. Subsequent heat treatment in a controlled atmosphere produces coatings with the degree of corrosion resistance approaching that of stainless steel and the high-nickel alloys. The coatings have little porosity and high resistance to heat and abrasion.

Nitrided

Nitriding is a means of improving wear resistance. In the most widely used process, steel is exposed to gaseous NH₄ at a temperature (about 538°C) suitable for the formation of metallic nitrides. The hardest cases are obtained with aluminum-bearing steels such as the Nitralloys. Where lower hardness is acceptable, steels containing aluminum, such as medium-carbon steels containing chromium and molybdenum, can be used.

Stainless steels can also be case hardened by nitriding. Straight chromium steels are more readily nitrided than Ni–Cr steels, although both are used. Tool steels can also be given a thin hard case.

Nitriding produces minimal distortion. Some growth occurs, but this can be allowed for. In general, nitriding is used for the same applications as carburizing.

Siliconized

Substantial improvements in the wear resistance and hardness of steel and iron parts can be obtained by impregnating with silicon (about 14%). The most wear-resistant cases are formed on low-carbon, low-sulfur steels. High-carbon, low-sulfur steels can also be impregnated, although treatment time is longer. White and malleable iron can also be siliconized; siliconizing of gray irons is not recommended.

The case of a siliconized surface (about 5–10 mils) is rather brittle, with hardness varying from Rockwell B80–B85. Siliconized surfaces are virtually nongalling and are especially effective in resisting combined wear and corrosion.

Diffusion Coefficient

A factor of proportionality representing the amount of substance diffusing across a unit area through a unit concentration gradient in unit time.

Diffusion Porosity

The porosity that is caused by the diffusion of one metal into another during sintering of a powder metallurgy compact. Also known as the Kirkendall porosity.

Diffusion Welding

(1) A solid-state welding process that produces coalescence of the faying surfaces by the application of pressure at elevated temperature. The process does not involve macroscopic deformation, melting, or relative motion of parts. A solid filler metal (diffusion aid) may or may not be inserted between the faying surfaces. (2) Welding resulting primarily from solid-state diffusion across the interface of the intended joint. Some interfacial force may be applied but no significant deformation, apart from crushing of minor asperities, occurs. Heating to a temperature below the melting point of the parent materials may be applied. If diffusion produces a low-melting-point phase that becomes molten, the process may be more precisely termed liquid-phase diffusion welding. If no molten phase is produced, the process may be termed solid-phase diffusion welding.

See also *forge welding*, *hot pressure welding*, and *cold welding*.

Diffusion Zone

The zone of variable composition at the junction between two different materials, such as in welds or between the surface layer in the core of clad materials or sleeve bearings, in which inner diffusion between the various components has taken place.

Diffusion-Limited Current Density

The *current density*, often referred to as *limiting current density*, that corresponds to the maximum transfer rate that a particular species can sustain because of the limitation of diffusion.

Digging

A sudden erratic increase in cutting depth, or in the load on a cutting tool, caused by unstable conditions in the machine setup. Usually, the machine is stalled or either the tool or the workpiece is destroyed.

D

Digital Radiography (DR)

Radiographic imaging technology in which a 2D set of x-ray transmission measurements is acquired and converted to an array of numbers for display with a computer. *Computed tomography* systems normally have DR imaging capabilities. Also known as digital radioscopy.

Dilatant

A reversible increase in viscosity with increasing shear stress. Compare with *pseudo-plastic behavior*, *rheopectic material*, and *thixotropy*.

Dilatometer

An instrument for measuring the linear expansion or contraction in a metal resulting from changes in such factors as temperature and allotropy.

Diluent

In an *organosol*, a liquid component that has little or no solvating action on the resin. Its purpose is to modify the action of the dispersant. The term diluent is commonly used in place of the term plasticizer.

Dilution

The change in chemical composition of a welding filler metal caused by the admixture of the base metal or previously deposited weld metal in the deposited weld bead. It is normally measured by the percentage of base metal or previously deposited weld metal in the weld bead.

Dilution Factor

When diluting a sample, the ratio of the final volume or mass after dilution to the volume or mass of the sample before dilution.

Dimensional Change

Object shrinkage or growth resulting from sintering a powder metal-lurgy compact.

Dimensional Stability

(1) A measure of dimensional change caused by such factors as temperature, humidity, chemical treatment, age, or stress (usually expressed as Δ units per unit). (2) The ability of a plastic part to retain the precise shape in which it was molded, cast, or otherwise fabricated.

Dimer

A substance (comprising molecules) form from two molecules of a *monomer*.

Dimerization

The formation of a *dimer*.

Dimethylglyoxime Test

A spot test to detect the presence of nickel in steel. A spot applied to the surface in question turns red in response to nickel.

Dimpled Rupture

A fractographic term describing *ductile fracture* that occurs through the formation and coalescence of microvoids along the fracture path. The fracture surface of such a ductile fracture appears dimpled when observed at high magnification and usually is most clearly resolved when viewed in a scanning electron microscope.

Dimples

Shallow indentations in a surface. They may be a manufacturing defect or they may be deliberate, for example, to locate the heads of fasteners. See also *dimpled fracture*.

Dimpling

(1) The stretching of a relatively small, shallow indentation into sheet metal. (2) In aircraft, the stretching of metal into a conical flange for a countersunk head rivet.

Dingot

An oversized *derby* (possibly a ton or more) of a metal produced in a bomb reaction (such as uranium from uranium tetrafluoride reduced with magnesium). For these metals, the term “ingot” is reserved for massive units produced in vacuum melting and casting. See also *bis-cuit* and *derby*.

Dinking

Cutting of nonmetallic materials or light-gauge soft metals by using a hollow punch with a knifelike edge acting against a wooden fiber or resiliently mounted metal plate.

Dip Brazing

A brazing process in which the heat required is furnished by a molten chemical or metal bath. When a molten chemical bath is used, the bath may act as a flux. When a molten metal bath is used, the bath provides the filler metal.

Dip Casting

In forming plastics, the process of submerging a hot mold into a resin. After cooling, the product is removed from the mold.

Dip Coat

(1) In the solid mold technique of investment casting, an extremely fine ceramic precoat applied as a slurry directly to the surface of the pattern to reproduce maximum surface smoothness. This coating is surrounded by coarser, less expensive, and more permeable investment to form the mold. (2) In the shell mold technique of investment casting, an extremely fine ceramic coating called the first coat, applied as a slurry directly to the surface of the pattern to reproduce maximum surface smoothness. The first coat is followed by other dip coats of different viscosity and usually containing different

grading of ceramic particles. After each dip, coarser stucco material is applied to the still wet coating. A buildup of several coats forms an investment shell mold. See also *investment casting*.

Dip Coating

Applying a plastic coating by dipping the article to be coated into a tank of melted resin or plastisol and then chilling the adhering metal.

Dip Plating

This is the same as *immersion plating*.

Dip Soldering

A soldering process in which the heat required is furnished by a molten metal bath that provides the solder filler metal.

Dip Transfer (in Welding)

See *metal transfer*.

Diphase Cleaning

Removing *soil* by an emulsion that produces two phases in the cleaning tank: a solvent phase and an aqueous phase. Cleaning is affected by both solvent action and emulsification.

Diphenyl Oxide Resins

Thermosetting resins based on diphenyl oxide and possessing excellent handling properties and heat resistance.

Dipole

A pair of equal and opposite separated charges, for example, a bar magnet.

Direct (Forward) Extrusion

See *extrusion*.

Direct Chill Casting

A continuous method of making ingots for rolling or extrusion by pouring the metal into a short mold. The base of the mold is a platform that is gradually lowered while the metal solidifies the frozen shell of metal acting as a retainer for the liquid metal below the wall of the mold. The ingot is usually cooled by the impingement of water directly on the mold or on the walls of the solid metal as it is lowered. The length of the ingot is limited by the depth in which the platform can be lowered; therefore, it is often called semicontinuous casting.

Direct Current Arc Furnace

An electric-arc furnace in which a single electrode positioned at the center of the furnace roof is the *cathode* of the system. Current passes from the electrode through the *charge* or bath to a cathode located at the bottom of the furnace. Current from the bottom of

the furnace then passes through the furnace refractories to a copper base plate to outside cables. It is used in the production of ferroalloys, carbon and alloy steels, and stainless steels. See also *arc furnace*.

Direct Current Casting

This is the same as *cathodic cleaning*.

Direct Current Electrode Negative (DCEN)

The arrangement of direct current arc welding leads in which the work is the positive pole and the electrode is the negative pole of the welding arc. See also *straight polarity*.

Direct Current Electrode Positive (DCEP)

The arrangement of direct current arc welding leads in which the work is the negative pole and the electrode is the positive pole of the welding arc. See also *reverse polarity*.

Direct Current Reverse Polarity (DCRP)

See *reverse polarity* and *direct current electrode positive*.

Direct Current Straight Polarity (DCSP)

See *straight polarity* and *direct current electrode negative*.

Direct Fired

Furnaces in which the stream of fuel is injected into, and burnt in, the chamber and combustion products surround the charge.

Direct Injection Burner

A burner used in flame emission and atomic absorption spectroscopy in which the fuel and oxidizing gases emerge from separate ports and are mixed in the flame itself. One of the gases, usually the oxidant, is used for nebulizing the sample at the tip of the burner.

Direct Quenching

(1) Quenching carburized parts directly from the carburizing operation. (2) Also used for quenching pearlitic malleable parts directly from the malleabilizing operation. See *case hardening*.

Direct Sintering

In powder metallurgy, a method whereby the heat needed for sintering is generated in the body itself, such as by induction or resistance heating. This is in contrast with *indirect sintering*.

Direct Stress

Simple tensile or compressive stresses developed by axial loads, as opposed to the more complex stresses developed by torsion or bending.

D

Directed Metal Oxidation Process (DIMOX)

This process is based on the reaction of a molten metal with an oxidant, usually a gas, to form a ceramic matrix. Unlike the sintering process, in which the ceramic powders and fillers are consolidated under heat, directed metal oxidation grows the ceramic-matrix material around the reinforcements.

Examples of ceramic matrices that can be produced by the DIMOX-directed metal oxidation process include Al_2O_3 , Al_2Ti_5 , AlN , TiN , ZrN , TiC , and ZrC . Filler materials can be anything chemically compatible with the ceramic, parent metal, and growth atmosphere.

The first step in the process involves making a shaped preform of the filler material. Preforms consisting of particles are fabricated with traditional ceramic-forming techniques, while fiber preforms are made by weaving, braiding, or laying up woven cloth. Next, the preform is put in contact with the parent metal alloy. A gas-permeable growth barrier is applied to the surfaces of this assembly to limit its shape and size.

The assembly, supported in a suitable refractory container, is then heated in a furnace. For aluminum systems, temperatures typically range from 899°C to 1149°C. The parent metal reacts with the surrounding gas atmosphere to grow the ceramic reaction product through and around the filler to form a ceramic-matrix composite (CMC).

Capillary action within the growing ceramic matrix continues to supply molten alloy to the growth front. There, the reaction continues until the growing matrix reaches the barrier. At this point, growth stops, and the part is cooled to ambient temperature. To recover the part, the growth barrier and any residual parent metal are removed. However, some of the parent metal (5%–15% by volume) remains within the final composite in micron-sized interconnected channels.

Traditional ceramic processes use sintering or hot pressing to make a solid CMC out of ceramic powders and filler. Part size and shapes are limited by equipment size and the shrinkage that occurs during densification of the powders can make sintering unfeasible. Larger parts pose the biggest shrinkage problem. Advantages of the DIMOX process include no shrinkage because matrix formation occurs by a growth process. As a result, tolerance control and large part fabrication can be easier with directed metal oxidation.

In addition, the growth process forms a matrix whose grain boundaries are free of impurities or sintering aids. Traditional methods often incorporate these additives, which reduce high-temperature properties. And cost comparison shows the newer process is a promising replacement for traditional methods.

Direct-Fired Tunnel-Type Furnace

A continuous-type furnace is where the work is conveyed through a tunnel-type heating zone, and the parts are hung on hooks or fixtures to minimize distortion.

Directional Property

Property whose magnitude varies depending on the relation of the test axis to a specific direction within the metal. The variation results from preferred orientation or from fibering of constituents or inclusions.

Directional Solidification

Controlled solidification of molten metal in a casting so as to provide feed metal to the solidifying front of the casting.

Directionality

The variation in properties observed when some materials are tested in differing directions relative to the axis of the material. The material may be cast in which case any variation will merit this term. However, virtually all plate and sheet materials have inferior properties in the thickness direction, so in such cases the term usually refers to differences between properties along and across the directions. See also *preferred orientation*.

Directionally Solidified Castings

Investment castings produced by *directional solidification* that exhibit an oriented columnar structure.

Dirt Content

A measure of the size and concentration of foreign particles present in a lubricant. Dirt content is usually reported as the number of particles per cubic centimeter, for specified particle sizes.

Disappearing Filament Pyrometer

See *pyrometry*.

Disassociate Separate

Often a reversible process or brief duration of separation is implied.

Disassociated Ammonia

A frequently used sintering atmosphere. See also *cracked gas*.

Disassociation

As applied to heterogeneous equilibria, the transformation of one phase into two or more phases of different composition. Compare with *order–disorder transformation*.

Disassociation Pressure

At a designated temperature, the pressure at which a metallic phase will transform into two or more phases of different compositions.

Disbond

In adhesive bonded structures, an area within the bonded interface between two adherends in which adhesion failure or separation has occurred. Also, colloquially, an area of separation between two laminae in the finish laminate (in this case, the term delamination is normally preferred). See also *debond*.

Disbondment

The destruction of adhesion between a coating and the surface coated.

Discard

Material scrapped from the tops of ingots, or the ends of extrusions and bars, etc., because of the inevitable deficiencies in quality at such positions.

Discontinuity

(1) Any interruption in the normal physical structure or configuration of a part, such as cracks, laps, seams, inclusions, or porosity. A discontinuity may or may not affect the utility of the part. (2) An interruption of the typical structure of a weldment, such as a lack of homogeneity in the mechanical, metallurgical, or physical characteristics of the material, or weldment. A discontinuity is not necessarily a defect. See also *defect* and *flaw*.

Discontinuous Precipitation

Precipitation from a supersaturated solid solution in which the precipitate particles grow by short-range diffusion, accompanied by recrystallization of the matrix in the region of precipitation. Discontinuous precipitates grow into the matrix from nuclei near grain boundaries, forming cells of alternate lamellae of precipitate and depleted (and recrystallized) matrix. It is often referred to as cellular or nodular precipitation. Compare with *continuous precipitation* and *localized precipitation*.

Discontinuous Sintering

Presintering or sintering of the subjects in a furnace according to a specified cycle that is tailored to the charge, for example, batch sintering, bell furnace sintering, box furnace sintering, and induction furnace sintering.

Discontinuous Yielding

(1) The nonuniform plastic flow of a metal exhibiting a yield point in which plastic deformation is inhomogeneously distributed along the gauge length. Under some circumstances, it may occur in metals not exhibiting a distinct yield point, either at the onset of or during plastic flow. (2) It occurs because grains are randomly oriented so some will deform before the others. The effect is most obvious with a coarse grain size and in material with a pronounced yield point.

Discrete

In its metallurgical context, this usually refers to features, such as particles in a microstructure, that are individually distinct and separate from their fellows.

Dished

Showing a symmetrical distortion of a flat or curved section of a plastic object so that, as normally viewed, it appears concave, or more concave than intended.

Dishing

Forming a shallow concave surface, the area being large compared to the depth.

Disinfectants

Materials used for killing germs, bacteria, or spore, thus eliminating causes of diseases or bad odors in factories and warehouses or in oils and compounds. The term *antiseptic* is employed in a similar sense in medicine, and the term *germicide* is often used for industrial disinfectants. Some disinfectants are also used as preservatives

for leather and other materials, especially chlorine and chlorine compounds. *Phenol* is one of the best-known disinfectants, and the germ-killing power of other chemicals is usually based on a comparison with it. Practically, all bacteria are killed in a few minutes by a 3% solution of phenol in water, but phenol has the disadvantage of being irritating to skin. Industrial disinfectants are usually sold as concentrates to be diluted to the equivalent of a 3%–5% solution of phenol.

Too large a proportion of disinfectants in oils, solutions, or the air may be injurious to workers, so the advice of health officials is ordinarily obtained prior to general use. Creosote oil and cresylic acid are employed in emulsions and disinfecting sprays and dips, but continuous contact with creosote may be injurious. *Formaldehyde* has high germicidal power and is used for hides and leather, and some air sprays may contain chemicals such as chlorophyll that unite with moisture in the air to produce formaldehyde. But formaldehyde is not generally recommended for odor control, as it is an *anesthetizer*. It densifies the olfactory receptors so that the individual is no longer able to detect the odor. *Masking agents*, which introduce a stronger, more pleasant odor, are likewise not a recommended method of disinfecting. They do not destroy the undesirable odor and may permit raising the total odor level to unhealthy proportions. Elimination of odors requires chemicals that neutralize or destroy the cause of the odors without causing undesirable effects.

The silver ion is an effective cleanser of water that contains bacteria that reduce sulfur-bearing enzymes, and silver sterilization is done with silver oxides on activated carbon or with organic silver compounds. The safe limit of silver and water for human consumption is specified by the U.S. Health Service as 10 ppb, and as with many other disinfectants, the use requires competent supervision. Among other metals, mercury is effective as an antibacterial agent in the form of *mercuric chloride*. Several organic mercurials are used as antiseptics, such as the *Mercurochrome* and *Metaphen* of Abbott Laboratories and *Merthiolate* of Eli Lilly and Co. Antiseptic atmospheres may be produced by spraying *chloramine T*, iodine, or argyrols. *Iodine* is a strong bactericidal antiseptic and is commonly used as a 2% tincture.

A 3%–5% solution of *hydrogen peroxide* is used as an antiseptic, although the chemical can cause corrosive burns at concentrations exceeding 25%. Compounds of various metals, such as iron manganese and cobalt, enhance peroxide's bactericidal action. Hydrogen peroxide is often trapped in *urea*, forming a solid containing up to 35% peroxide. *Ozone* generators are becoming popular for disinfecting swimming pools. Zinc peroxide and benzoyl peroxide are especially effective as antiseptic dressings.

The antiseptic throat lozenge known as *Sucrets* has a base of sugar and glucose, with hexylresorcinol and a flavor.

Disk Grinding

Grinding with the flat side of an abrasive disk or segmented wheel. It is also called *vertical-spindle surface grinding*.

Disk Machine

In tribology, a testing machine for rolling or rolling/sliding contact in which two disk-shaped rollers, with parallel axes of rotation, make tangential contact on their circumferences as they move relative to one another.

Disk Piercer

See *tube making*.

D

Dislocation

A linear imperfection in a crystalline array of atoms. Two basic types are recognized: (1) An edge dislocation corresponds to the row of mismatched atoms along the edge formed by an extra, partial plane of atoms within the body of a crystal. (2) A screw dislocation corresponds to the axis of a spiral structure in a crystal, characterized by a distortion that joins normally parallel planes together to form a continuous helical ramp (with a pitch of one interplanar distance) winding about the dislocation. The most prevalent is the so-called mixed dislocation, which is any combination of an edge dislocation and a screw dislocation. (3) Dislocation is a major, long-range, irregularity in the alignment of planes of atoms on the crystal lattice. Two forms of dislocations are the edge dislocation and the screw dislocation. A perfect crystal lattice would be extremely strong and resistant to plastic deformation. However, the presence of dislocations reduces the strain to about a thousandth of the theoretical level and facilitates plastic deformation. The principle can be visualized simplistically by considering two planes of atoms that are going to slide across each other. If the structures of the two planes match perfectly, then movement will not occur until the load is sufficient to overcome the bonds between every atom and its neighbor on the next plane. However, if a line of atoms is missing from one plane, then the load need only be sufficient to overcome the bonds on a single line of atoms. The dislocation will move one atomic spacing at a time, and when it has completed its movement across a crystal, it will leave a step with a height of one atomic space. An analogy often quoted to illustrate the low stress needed is the requirement to move a long strip of carpet for a short distance. If one end is pulled, a very large load is necessary to achieve any movement. However, a rod, representing a dislocation, can be put under the width of the carpet at one end and then pulled underneath the carpet to the other end. The load required is small and the carpet will be moved forward by a small increment. The movement of an individual dislocation is measured in terms of its Burgers vector, which identifies the total lattice translation resulting from the passage of the dislocation. Clearly, large numbers of dislocation movement are necessary to achieve any discernible deformation, but in practice metals contain, or can develop, immense numbers of dislocations. The movement of a series of dislocations along an individual plane is termed glide. However, as the dislocations move, they become mutually entangled or locked by grain boundaries and other microstructural features. This necessitates higher stresses to cause further deformation, that is, strain hardening occurs. Ultimately, further deformation is impossible and an increasing stress will initiate failure at the most severe *log jam* of dislocations. As mentioned earlier, although some dislocations are present in cast or annealed material, many others can be created by the imposed stress and associated deformation. The creation mechanism, termed a Frank–Read source, comprises an initial dislocation anchored at its ends. A shear load acting on the dislocation causes it to bulge outwards and then pivot round the anchored ends until it forms a complete dislocation loop. In the process, the original dislocation reestablishes itself to initiate further loops.

Dislocation Climb

A thermally activated, time-dependent mechanism in which the creation and diffusion of vacancies allows a dislocation to move or *climb* onto a neighboring plane.

Dislocation Etching

Etching of exit points of dislocations on a surface. It depends on the strain field ranging over a distance of several atoms. Crystal figures

(edge pits) are formed at exit points. For example, edge pits for cubic materials are cube faces.

Dislocation Pending/Locking

The restraint on movement of a dislocation resulting from its interaction with some microstructural feature such as a precipitate, interstitial atom, or another dislocation.

Disordered Structure

The crystal structure of a solid solution in which the atoms of different elements are randomly distributed relative to the available lattice sites. This is in contrast with *ordered structure*.

Disordering

Forming a lattice arrangement in which the solute and solvent atoms of a solid solution occupy lattice sites at random. See also *ordering* and *superlattice*.

Dispersant Additive

In lubrication technology, an additive capable of dispersing cold oil sludge.

Dispersant Oil

A heavy-duty oil containing a dispersant additive.

Dispersing Agent

A substance that increases the stability of a suspension of powder particles in a liquid medium by the deflocculation of the primary particles.

Dispersion

Finely divided particles of a material in suspension and another substance.

Dispersion Hardening/Strengthening

Hardening induced by numerous fine inert particles introduced into the material and evenly distributed throughout the structure including within the grains. The particles are not soluble in the matrix even if the material is melted and hence are not an alloying addition in the usual sense of the term. However, they serve the same purpose as precipitates in that they can lock dislocations, impede slip, and increase strength, including creep strength. In addition, as they remain insoluble, they can impede grain growth and even inhibit recrystallization and so further enhance high-temperature performance. The particles may be introduced either by addition to the molten metal in the form of an inert powder or by a powder metal technique so that after processing, the material comprises the metal matrix plus oxide particles derived from the oxide film that originally covers the powder.

Dispersion-Strengthened Material

A metallic material that contains a fine dispersion of nonmetallic phase(s), such as Al_2O_3 , MgO , SiO_2 , CdO , ThO_2 , Y_2O_3 , or ZrO_2

singly or in combination, to increase the hot strength of the metallic matrix. Examples include dispersion-strengthened copper (Al_2O_3) used for welding electrodes, silver (CdO) used for electrical contacts, and nickel–chromium (Y_2O_3) superalloys used for gas turbine components. See also *mechanical alloying*.

Dispersion-Strengthened Metals

Particulate composites in which a stable material, usually an oxide, is disbursed throughout a metal matrix. The particles are less than $1\text{ }\mu\text{m}$ in size, and the particle volume fraction ranges from only 2% to 15%. The matrix is the primary load bearer, while the particles serve to block dislocation movement and cracking in the matrix. Therefore, for a given matrix material, the principal factors that affect mechanical properties are the particle size, the interparticle spacing, and the volume fraction of the particle phase. In general, strength, especially at high temperatures, improves as interparticle spacing decreases. Depending on the materials involved, dispersion-hardened alloys are produced by either powder metallurgy, liquefied-metal, or colloidal techniques. They differ from precipitation-hardened alloys in that the particle is usually added to the matrix by nonchemical means. Precipitation-hardened alloys derive their properties from compounds that are precipitated from the matrix through heat treatment.

There is a rather wide range of dispersion-hardened alloy systems. Those of aluminum, nickel, and tungsten, in particular, are commercially significant. Tungsten–thorium, a lamp-filament material, has been in use for more than 30 years. Dispersion-hardened aluminum alloys, known as SAP alloys, are composed of aluminum and Al_2O_3 and have good oxidation and corrosion resistance plus high-temperature stability and strength considerably greater than that of conventional high-strength aluminum alloys. Another dispersion-hardened metal, TD nickel, has dispersion of thoria in a nickel matrix. It is three to four times stronger than pure nickel at 871°C – 1316°C . TD-Ni–Cr has also been produced for increased resistance to high-temperature oxidation. Other metals that have been dispersion strengthened include copper, lead, zinc, titanium, iron, and tungsten alloys. The copper is used for resistance-welding (spot-welding) tips.

Dispersoid

Finely divided particles of relatively insoluble constituents visible in the microstructure of certain metallic alloys.

Displacement

The distance that a chosen measurement point on the test specimen displaces normal to the crack plane. See also *crack opening displacement* and *crack plane orientation*.

Displacement Angle

In filament winding, the advancement distance of the winding ribbon on the equator after one complete circuit.

Displacement Controlled Loading

A term applied to forms of loading during testing (or service) where the load is applied by a rigid structure of, effectively, fixed dimensions so that if the test piece extends after initial loading, the load and stress fall. An example is a high-temperature flange joint with bolts passing through it. Because of the difference in cross sections,

the type bolts experience considerable tensile strain but the flanges are hardly compressed. As the bolts creep, converting elastic strain to permanent creep strain, the tensile stresses in the bolts fall so the closure forces on the flanges reduce, leading to leakage. The alternative is load controlled loading in which the load does not vary as strain occurs. An example is a weight hanging freely on a rod. If the rod extends, the load due to the weight obviously does not change, but if the rod cross section reduces by creep, the stress increases.

Display Resolution

Number of picture elements (pixels) per unit distance in the object.

Disproportionation

In the processing of plastics, termination by chain transfer between macroradicals to produce a saturated and an unsaturated polymer molecule.

Disrupted Strength

The stress at which a metal fractures under hydrostatic tension.

Dissimilar Metal Joint

In its general sense, any joint between different metals. Generalizing, such joints can be difficult to make by processes such as welding and often present problems in service because of differences in the chemical, electrochemical, and physical properties. The term is often used in a more specific sense regarding welded joints between austenitic and ferritic steel pipe work in power plants. The primary motivation to use two materials is cost; the low alloy ferritic steels are relatively cheap compared with the austenitic steels, but the latter have the superior creep properties required for the higher-temperature zones. Sound welds are fairly easy to achieve but high-temperature operation in the 500°C – 600°C region causes considerable problems. Carbon tends to diffuse from the ferritic to the austenitic so the ferritic material is weakened; the expansion coefficients differ considerably so differential expansion and contraction causes large stresses that are superimposed on the stresses arising from internal pressure; and finally, the two materials have distinctly different oxidation characteristics. Collectively, these effects lead to premature creep damage, usually in the ferritic steel close to the weld and to a wedge-shaped oxide band penetrating from the exterior, again in the ferritic material close to the weld.

Dissipation Factor, Electrical

See *quality factor* (2).

Dissolution

The process of one material dissolving another.

Dissolution Etching

Development of microstructure by surface removal.

Distortion

Any deviation from an original size, shape, or contour that occurs because of the application of stress or the release of residual stress.

D

Distortion (Composites)

In fabric, the displacement of fill fiber from the 90° angle (right angle) relative to the warp fiber, while in a laminate, the displacement of the fibers (especially at radii), relative to their idealized location, due to motion during lay-up and cure.

Distributed Impact Test

In impingement erosion testing, an apparatus or method that produces a spatial distribution of impacts by liquid or solid bodies over an exposed surface of a specimen. Examples of such tests are those employing liquid sprays or simulated rainfields. If the impacts are distributed uniformly over the surface, the term uniformly distributed impact test may be used.

Distribution Contour

The shape of the particle size distribution curve.

Distribution Ratio

See *partition law*.

Disturbed Metal

The cold-work metal layer formed at a polished surface during the process of mechanical grinding and polishing.

Divariant Equilibrium

See *bivariate equilibrium*.

Divided Cell

A cell containing a diaphragm or other means for physically separating the *anolyte* from the *catholyte*.

Dividing Cone

A conical powder heap that is divided into quarters for the purpose of sample taking.

Divorced Eutectic

A demographic appearance in which the two constituents of a eutectic structure appear as massive phases rather than the finely divided mixture characteristic of normal eutectics. Often, one of the constituents of the eutectics is continuous and indistinguishable from an accompanying proeutectic constituent.

Divorced Pearlite

Pearlite whose original lamellar structure has broken down by diffusion, at an elevated temperature but below the lower critical, to form spheroidized carbides in a ferrite matrix. See *steel*.

DN Value

The product of bearing bore diameter in millimeters and speed in revolutions per minute.

Doctor Blade or Bar

In forming plastics, a straight piece of material used to spread resin, as in application of a thin film of resin for use in hot-melt prepregging or for use as an adhesive film. It is also called *paste metering blade*.

Doctor Roll

In applying adhesives, a roller mechanism that is revolving at a different surface speed, or in an opposite direction, resulting in a wiping action for regulating the adhesive supplied to the spreader roll.

Doily

In filament winding of composites, the planar reinforcement applied to a local area between windings to provide extra strength in an area where a cutout is to be made, for example, port openings. It is usually placed at the knuckle joints of cylinder to dome.

Dolly

A massive support held behind material being struck. Its inertia results in the material deforming rather than just bouncing away. The dolly is not normally shaped to the intended profile.

Dolomite

Dolomite is the carbonate material $\text{CaMg}(\text{CO}_3)_2$, often with small amounts of iron, manganese, or excess calcium, which replace some of the magnesium; cobalt, zinc, lead, and barium are more rarely found.

Dolomite is a very common mineral, occurring in a variety of geologic settings. It is often found in ultrabasic igneous rocks, notably in carbonates and serpentinites; in metamorphosed carbonate sediments, where it may crystallize to form dolomite marbles; and in hydrothermal veins. The primary occurrence of dolomite is in sedimentary deposits, where it constitutes the major component of dolomite rock and is often present in limestones.

Dolomite is normally white or colorless with a specific gravity of 2.9 and a hardness of 3.5–4 on Mohs scale.

Dolomite Brick

A calcium magnesium carbonate used as a refractory brick that is manufactured substantially or entirely of *dead-burned* dolomite.

Domain (Magnetic)

A substructure in a ferromagnetic material within which all the elementary magnets (electron spins) are held aligned in one direction by interatomic forces; if isolated, a domain would be a saturated permanent magnet.

Domain (Plastics)

A morphological term used in noncrystalline systems, such as block copolymers, in which the chemically different sections of the chain separate, generating two or more amorphous phases.

Dome

In filament winding, the portion of a cylindrical container that forms the spherical or elliptical shell ends of the container.

Domed

Showing a symmetrical distortion of a flat or curved section of a plastic object so that, as normally viewed, it appears convex, or more convex than intended.

Donnan Exclusion

In *ion chromatography*, the mechanism by which an ion-exchange resin can be made to act like a semipermeable membrane between an interstitial liquid and liquid occluded inside the resin particles. Highly ionized molecules are excluded from the resin particles by electrostatic forces; weakly ionized or nonionized molecules may pass through the membrane.

Donor

An element in a semiconductor. See *semiconductor*.

Dopant

- (1) An impurity introduced under highly controlled conditions in very small but accurately known quantities into a semiconductor material, such as silicon. Dopants modify the electrical characteristics of the silicon by creating *p* or *n* regions and hence *p-n* junctions.
- (2) A material added to a polymer to change a physical property.

Doped Solder

A solder containing a small amount of an element intentionally added to ensure retention of one or more characteristics of the materials on which it is used.

Doping

In powder metallurgy, the addition of a small amount of an activator to promote sintering.

Doppler Effect

The change in the observed frequency of an acoustic or electromagnetic wave due to the relative motion of source and observer. See also the *Doppler shift*.

Doppler Shift

The amount of change in the observed frequency of a wave due to the Doppler effect, usually expressed in hertz. See also the *Doppler effect*.

Doré Silver

Crude silver containing a small amount of gold, obtained after removing lead in a cupelling furnace. This is the same as doré bullion and doré metal.

Dosimeter

A device for measuring radiation-induced signals that can be related to absorb the dose (or energy deposited) by radiation in materials and is calibrated in terms of the appropriate quantities and units. It is also called the dose meter.

Dot Map

See *x-ray map*.

Double Aging

Employment of two different aging treatments to control the type of precipitate formed from a supersaturated matrix in order to obtain the desired properties. The first aging treatment, sometimes referred to as intermediate or stabilizing, is usually carried out at higher temperature than the second.

Double Anneal

A double heat treatment cycle in which steel is first subject to a form of high temperature normalizing and then to a conventional anneal. The initial heating to well above the upper critical promotes homogenization and coalesces or blunts manganese sulfide inclusions. Rapid cooling to just below the lower critical then inhibits the formation of a coarse grain size. The steel is then immediately reheated to just above the upper critical and finally slow cooled. This produces a fully softened fine-grained material.

Double Arcing (Plasma Arc Welding and Cutting)

A condition in which the main arc does not pass through the constricting orifice but transfers to the inside surface of the nozzle. A secondary arc is simultaneously established between the outside surface of the nozzle and the workpiece. Double arcing usually damages the nozzle.

Double Cone Mixer

A vessel in the shape of two cones abutting at their base that rotates on an axis through the base and that provides thorough mixing or blending of a powder by cascading.

Double Etching

In metallography, use of two etching solutions in sequence. The second etchant emphasizes a particular microstructural feature.

Double Layer

The interface between an *electrode* or a suspended particle and an *electrolyte* created by charge-charge interaction leading to an alignment of oppositely charged ions at the surface of the electrode or particle. The simplest model is represented by a parallel plate condenser.

Double Pressing

A method whereby compaction of metal powders is carried out in two steps. It may involve removal of the compact from the die after the first pressing for the purpose of storage, drying, baking, presintering, sintering, or other treatment, before reinserting into a die for the second pressing.

Double Salt

A compound of two salts that crystallize together in a definite proportion.

D**Double Sintering**

In powder metallurgy, a method consisting of two separate sintering operations with a shape change by machining or coining performed in between.

Double Skin

A layer of metal on the surface of a casting separated from the underlying material by an oxide film. It is produced during casting when, after solidification commences at the mold surface, the molten metal recedes temporarily exposing the newly solidified material to the atmosphere. Although the molten metal returns to fill the mold, the oxidized layer remains substantially intact as a major weakness.

Double Spread

The application of adhesives to both adherends of a joint.

Double Tempering

A treatment in which a quench-hardened ferrous metal is subjected to two complete tempering cycles, usually at substantially the same temperature, for the purpose of ensuring completion of the tempering reaction in promoting stability of the resulting microstructure.

Double-Acting Hammer

A forging hammer in which the ram is raised by admitting steam or air into a cylinder below the piston and the blow intensified by admitting steam or air above the piston on the downward stroke.

Double-Action Die

A die designed to perform more than one operation in a single stroke of the press.

Double-Action Forming

Forming or drawing in which more than one action is achieved in a single stroke of the press.

Double-Action Mechanical Press

A press having two independent parallel movements by means of two slides, one moving within the other. The inner slide or plunger is usually operated by a crankshaft; the outer or blankholder slide, which dwells during the drawing operation, is usually operated by a toggle mechanism or by cams. See also *slide*.

Double-Action Press

A press that provides pressure from two sides, usually opposite from each other, such as from top to bottom.

Double-Bevel Groove Weld

A groove weld in which the joint edge of one member is beveled from both sides.

Double-J Groove Weld

A groove weld in which the joint edge of one member is in the form of two Js, one from either side.

Doubler

In filament winding of composites, a local area with extra reinforcement, wound integrally with the part or wound separately and fastened to the part. See also *tabs*.

Double-Shot Molding

In forming plastics, a means of producing two color parts and/or two different thermoplastic materials by successive molding operations.

Double-U Groove Weld

A groove weld in which each joint edge is in the form of two Js or two half Us, and one from either side of the member.

Double-V Groove Weld

A groove weld in which each joint edge is beveled from both sides.

Dovetailing (Thermal Spraying)

A method of surface roughening involving angular undercutting to interlock the spray deposit.

Dow Process

A process for the production of magnesium by electrolysis of molten magnesium chloride.

Dowel

(1) In casting, a wooden or metal pin of various types used in the parting surface of parted patterns and core boxes. (2) In die-casting dies, metal pins to ensure correct registry of cover and ejector halves.

Down Cutting

See the preferred term *climb cutting*.

Down Milling

See the preferred term *climb milling*.

Downgate

This is the same as *sprue*.

Downhand

See the preferred term *flat position*.

Downhand Welding

See *flat position welding*, the usually preferred term.

Downslope Time (Automatic Arc Welding)

The time during which the current is changed continuously from final taper current or welding current to final current.

Downslope Time (Resistance Welding)

The time during which the welding current is continuously decreased.

Downsprue

This is the same as *sprue*.

Downtime

The period or total time that equipment or production facilities are not available. Plan maintenance activities may be included or excluded depending on site practice.

Draft

(1) An angle or taper on the surface of a pattern, core box, punch, or die (or of the parts made with them) that facilitates removal of the parts from a mold or die cavity or a core from a casting. (2) The change in cross section that occurs during rolling or cold drawing.

Draft Angle

(1) The angle of a taper or a mandrel or mold that facilitates removal of the finished plastic part. (2) The angle of taper, usually 5°–7°, given to the sides of a forging in the sidewalls of the die impression. See the term *backhand welding*.

Drag

The bottom section of a *flask*, *mold*, or *pattern*. See *cope*.

Drag (Thermal Cutting)

The offset distance between the actual and the theoretical exit points of the cutting oxygen stream measured on the exit surface of the material.

Drag Angle

In welding, the angle between the axis of the electrode or torch and a line normal to the plane of the weld when welding is being done with the torch positioned ahead of the weld puddle. See the *backhand welding*.

Drag Lines/Markings

The characteristic linear steps or serrations on a thermally cut face.

Drag Soldering

A process in which supported, moving printed circuit assemblies or printed wiring assemblies are brought in contact with the surface of a static pool of molten solder.

Drag Technique

A method used in manual arc welding wherein the electrode is in contact with the assembly being welded without being in short circuit. The electrode is usually used without oscillation.

Drag-In

Water or solution carried into another solution by the work and its associated handling equipment.

Dragout

Material inadvertently dragged from a treatment solution or molten bath by the component or handling equipment.

Drainage

Conduction of electric current from an underground metallic structure by means of a metallic conductor. Forced drainage is that applied to underground metallic structures by means of an applied electromotive force or sacrificial anode. Natural drainage is that from an underground structure to a more negative (anodic) structure, such as the negative bus of a trolley substation.

Drape

In fabricating composites, the ability of a fabric or prepreg to conform to a contoured surface.

Drape Forming

A method of forming thermoplastic sheet in which the sheet is clamped into a movable frame, heated, and draped over high points of the male mold. Vacuum is then pulled to complete the forming operation. It is also known as basic male mold forming.

Draw

A term used to denote the shrinkage or void that appears on the surface of a casting or within a casting.

Draw Bead

(1) An insert or riblike projection on the draw ring or hold-down surfaces that aids in controlling the rate of metal flow during deep-draw operations. Draw beads are especially useful in controlling the rate of metal flow in irregularly shaped stampings.

Draw Forging

See *radial forging*.

Draw Forming

A method of curving bars, tubes, or rolled or extruded sections in which the stock is bent around a *rotating form block*. Stock is bent by clamping it to the form block and then rotating the form block while the stock is pressed between the form block and a pressure die held against the periphery of the form block.

Draw Head

Set of rolls or dies mounted on a drawbench for forming a section from strip, tubing, or solid stock. See also *Turk's head rolls* and *drawbench*.

Draw Marks

See *scoring*, *galling*, *pickup*, and *die line*.

D

Draw Plate

(1) In metal forming, a circular plate with a hole in the center contoured to fit a forming punch; used to support the *blank* during the forming cycle. (2) In casting, a plate attached to a pattern to facilitate drawing of a pattern from the mold.

Draw Radius

The radius at the edge of a die or punch over which sheet metal is drawn.

Draw Ring

A ring-shaped die part (either the die ring itself or a separate ring) over which the inner edge of sheet metal is drawn by the punch.

Draw Stock

The forging operation in which the length of a metal mass (stock) is increased at the expense of its cross section; no *upset* is involved. The operation includes converting ingot to press bar using “V,” round, or flat dies.

Drawability

A measure of the formability of a sheet metal subject to a drawing process. The term is usually used to indicate the ability of a metal to be deep drawn. See also *drawing* and *deep-drawing*.

Drawbench

The machinery and associated equipment for drawing tube, wire, and rod, etc. It will typically include the table, that is, the bench, which carries the die block and replaceable die close rollers or slides, the gripping device (sometimes termed the head or the dog), the drawer chain, the drive motor, and associated equipment.

Draw-Down Ratio

In forming plastics, the ratio of the thickness of the die opening to the final thickness of the product.

Drawing

(1) A term used for a variety of forming operations, such as *deep-drawing* a sheet metal blank, redrawing a tubular part, and drawing rod, wire, and tube. The usual drawing process with regard to sheet metal working in a press is a method for producing a cuplike form from a sheet metal disc by holding it firmly between blankholding surfaces to prevent the formation of wrinkles while the punch travel produces the required shape. (2) The process of stretching a thermoplastic to reduce its cross-sectional area, thus creating a more orderly arrangement of polymer chains with respect to each other. (3) A misnomer for tempering (see *temper*).

Drawing (Pattern)

In foundry practice, removing a pattern from a mold or a mold from a pattern in production work.

Drawing Compound

(1) A substance applied to prevent *pickup* and *scoring* during drawing or pressing operations by preventing metal-to-metal contact of

the work and die. It is also known as *die lubricant*. (2) In metal-working, a lubricant having extreme-pressure properties. See also *extreme-pressure lubricant*.

Drawing Out

A stretching operation resulting from a forging a series of upsets along the length of the workpiece.

Drawn Fiber

Fiber for reinforced plastics with a certain amount of orientation imparted by the joint process by which it is formed.

Drawn Shell

An article formed by drawing sheet metal into a hollow structure having a predetermined geometric configuration.

Dresser

(1) Various tools for hammering and forging operations. In most cases the final shaping operation is involved. (2) A tool with a head formed from a number of freely rotating ridged disks. It is held against a rotating grindstone to dress, that is, restore, the profile. (3) A tool used for *truing* and *dressing* a grinding wheel.

Dressing

(1) Cutting, breaking down, or crushing the surface of a grinding wheel to improve its cutting ability and accuracy. (2) Removing dulled grains from the cutting face of a grinding wheel to restore cutting quality. (3) (of weld) Machining or grinding of the surface of a weld to modify its profile. It may be undertaken for cosmetic or technical purposes, for example, to reduce the reinforcement height, to flush it with the parent surfaces, or to remove defects at the toe. See also *flushing*.

Driers

Materials used for increasing the rapidity of the drying of paints and varnishes. The chief function of driers is to absorb oxygen from the air and transfer it to the oil, thus accelerating its drying to a flexible film. They are in reality catalyzers. Excessive use of driers will destroy the toughness of the film and cause the paint to crack. Solutions of driers are called *liquid driers*; it is in this form that *paint driers* are most used. Certain oils, such as tung oil, have inherent drying properties and are classified as drying oils but not as driers. Driers may be oxides of metals, but the most driers are metallic salts of organic acids. *Manganese acetate* is a common paint drier. It is pinkish, crystalline powder soluble in water and in alcohol and is used in strengths of 6%, 9%, and 12% metal. *Sugar of lead*, used as a drier, is *lead acetate*, a white, crystalline powder with a faint acetic acid odor, also used as a mordant in textile printing. It is known as *plumbous acetate* and *Goulard's powder*. Lead oleate is a drier made by the action of a lead salt on oleic acid. It is used for thickening lubricants. Cobalt octoate, which has about 12% cobalt in combination with hexoic acid, is used as a drier. *Cobalt driers* are twice as rapid in drying power as manganese driers, but two rapid drying often makes a wrinkled film that is desirable for some finishes but not for others.

Naphthenate driers are metallic salts made with naphthenic acids instead of fatty-oil acids. They are usually more soluble in paint solvents, and since the naphthenic acids can be separated into a wide range of molecular weights by distillation, a wider variety of characteristics can be obtained. *Sodium naphthenate*, with 8.6% metal content, and *potassium naphthenate*, with 13.1%, are powders that are good bodying agents and emulsifiers as well as driers. *Tin naphthenate*, with 20% tin, may be added to lubricating oils as an antioxidant. *Mercuric naphthenate*, with 29% mercury, retards the growth of bacteria and molds when added to finishes. *Barium naphthenate*, with 22.6% barium, has binding and hardening properties and is used in adhesives and in linoleum.

Drift

(1) A flat piece of steel of tapering width used to remove taper shank drills and other tools from their holders. (2) A tapered rod used to force mismatched holes into line for riveting or bolting. This is sometimes called a drift pin. (3) A small plain faced punch.

Drift test

A test in which a hard tapered mandrel is forced into a tube or hole to measure the materials capacity to distend without unacceptable damage.

Drill

(1) A rotary end-cutting tool used for making holes; it has one or more cutting lips and an equal number of helical or straight flutes for passage of chips and admission of cutting fluid. (2) A drill bit, that is, a rotating tool with cutting edges at its tip and flutes along the shank to lead away the swarf. (3) It is plunged axially into the workpiece to form, or drill, a cylindrical wall. (4) A drilling machine, that is, one in which a drill bit is mounted to drill holes in a workpiece.

Drill Rod

Tool-steel round rod made to a close degree of accuracy, generally not over or under 0.0005 in. (0.0127 mm) diameter size, and usually polished. It is employed for making drills, taps, reamers, and punches or for dowel pins, shafts, and rollers. Some mills also furnish square rods to the same accuracy under the name of drill rod. Common drill rod is of high-carbon steel hardened by quenching in water or in oil. The sizes are by the standard of drill gauges, with about 200 different diameters. The carbon content is usually from 0.9% to 1.05%, with 0.25 to 0.50 manganese, 0.10 to 0.50 silicon, and a maximum of 0.04 phosphorus or sulfur. It also comes in a high carbon with 1.50%–1.65% carbon and 0.15%–0.35% manganese. Drill rod can be obtained regularly in high-speed steels and in special alloy steels for dowel pins. *Needle wire* is a round tool-steel wire used for making needles, awls, and latch pins. *Needle tubing* for surgical instruments and radon implanters is stainless steel tubing. *Hypodermic tubing* is hard-drawn stainless steel tubing with a fine finish. Capillary tubing is also stainless steel but comes in lengths to 200 ft (61 m). *Drill steel*, for mine and quarry drills, comes in standard rounds, octagons, squares, and cruciform bars, solid or hollow, usually in carbon steel.

Drilling

Hole making with a rotary end-cutting tool having one or more cutting lips and one or more helical or straight flutes or tubes for the ejection of chips and the passage of a cutting fluid.

1. *Center drilling*: Drilling a conical hole in the end of a workpiece
2. *Core drilling*: Enlarging a hole with a chamfer-edged, multiple-flute drill
3. *Spade drilling*: Drilling with a flat blade drill tip
4. *Step drilling*: Using a multiple-diameter drill
5. *Gun drilling*: Using special straight flute drills with a single lip and cutting fluid at high pressures for deep hole drilling
6. *Oil hole or pressurized coolant drilling*: Using a drill with one or more continuous holes through its body and shank to permit the passage of a high pressure cutting fluid that emerges at the drill point and ejects chips

Drip Feed Lubrication

A system of lubrication in which the lubricant is supplied to the bearing surface in the form of drops at regular intervals. This is also known as *drop feed lubrication*.

Drip Test

Any test in which the material under test is subjected to a liquid drip of prescribed composition, size, and frequency to determine the response of the surface and any coating. The specimen is usually at a defined angle to the horizontal to ensure that the droplets run down the same track. The water drip test uses a drip of 0.05% sodium chloride in water.

Drive Fit/Driving Fit

This is the same as force fit except that more force, possibly in a press, may be required.

Drop

A casting imperfection due to a portion of the sand dropping from the cope or other overhanging sections of the mold.

Drop Etching

In metallography, placing of a drop of etchant on the polished surface.

Drop Forging/Hammer/Stamping

(1) Originally, a process in which the tup or hammerhead was allowed to fall under its own weight; now the term may be applied to fast acting vertical forges. The tup and anvil faces may be plain but usually carry dies to shape the component. (2) The forging obtained by hammering metal in a pair of closed dies to produce the form in the finishing impression under a *drop hammer*; forging method requiring special dies for each shape.

D

Drop Hammer

A term generally applied to forging hammers in which energy for forging is provided by gravity, steam, or compressed air. See also *airlift hammer*, *board hammer*, and *steam hammer*.

Drop Hammer Forming

A process for producing shapes by the progressive deformation of sheet metal in matched dies under the repetitive blows of a gravity-drop or power-drop hammer. The processes restricted to relatively shallow parts and thin sheet from approximately 0.6 to 1.6 mm (0.024 to 0.064 in.).

Droplet Erosion

Erosive wear caused by the impingement of liquid droplets on a solid surface. See also *erosion (erosive) wear*.

Drop Point

The temperature at which a drop falls from a grease through a specified orifice. The drop point does not necessarily represent the maximum operating temperature of a grease.

Drop-through

An undesirable sagging or surface irregularity, usually encountered when brazing or welding near the solidus of the base metal, caused by overheating with rapid diffusion or alloying between the filler metal and the base metal.

Dross

(1) The scum that forms on the surface of molten metal largely because of oxidation but sometimes because of the rising of impurities to the surface. (2) Oxide and other contaminants that form on the surface of molten solder.

Drum

A filler metal package type consisting of a continuous length of electrode wound or coiled within an enclosed cylindrical container.

Drum test

A test of the green strength of powder metallurgy compacts by tumbling them in a drum and examining the sharpness of the edges and corners.

Dry

To change the physical state of an adhesive on an adherend by the loss of solvent constituents by evaporation or absorption, or both. See also *cure* and *set*.

Dry and Baked Compression Test

An American Foundrymen's Society test for determining the maximum compressive stress that a baked sand mixture is capable of developing.

Dry Blend

Refers to a plastic molding compound containing all necessary ingredients mixed in a way that produces a dry, free-flowing, particulate material. This term is commonly used in connection with polyvinyl chloride molding compounds.

Dry Bond Adhesive

See *contact adhesive*.

Dry Coloring

Method commonly used by fabricators for coloring plastics by tumble blending uncolored particles of the plastic material with selected dyes and pigments.

Dry Copper

Tough pitch copper containing excessive quantities of copper oxide particles, hence of low ductility.

Dry Corrosion

See *gaseous corrosion*.

Dry Etching

In metallography, development of microstructure under the influence of gases.

Dry Fiber

In composites fabrication, a condition in which fibers are not fully encapsulated by resin during *pultrusion*.

Dry Friction

Friction that occurs between two bodies in the absence of lubrication. This term is inaccurate because it historically implies that there is no intentionally applied lubrication, when in fact solid lubrication conditions can be considered *dry*. Therefore, this term should not be used.

Dry Ice

Dry ice is a solid form of carbon dioxide, CO₂, which finds its largest application as a cooling agent in the transportation of perishables. It is nontoxic and noncorrosive and sublimates directly from a solid to a gas, leaving no residue. At atmospheric pressure it sublimates at -78.7°C, absorbing its latent heat of 573.1 kJ/kg. Including sensible heat absorption, the cooling effect per pound (kilogram) of dry ice is approximately 628.0 kJ at storage temperatures above -9°C and 581.5 kJ at lower temperatures. Slabs of dry ice can easily be cut and used in shipping containers for frozen foods, in refrigerated trucks, and as a supplemental cooling agent in refrigerator cars.

The manufacture of CO₂ gases is a chemical process. The gas is liquefied by compressing it to 6.2–6.9 MPa gauge in three stages of reciprocating compressors and then condensing it in water-cooled condensers. The liquid is expanded to atmospheric pressure where the temperature is below the triple point -56.6°C.

Dry Joint (Soldered or Brazed)

A joint with inadequate bonding due to the failure of the solder or braze filler metal to wet the parent metal surface. It results from contamination or lacquer flux. See also *cold joint*.

Dry Laminate

A laminate containing insufficient resin for complete bonding of the reinforcement. See also *resin-starved area*.

Dry Lay-Up

Construction of a laminate by the layering of preimpregnated reinforcement (partly cured resin) in a female mold or on a male mold, usually followed by bag molding or autoclave molding. See also *vacuum bag molding*.

Dry Lubricant

See *solid lubricant*.

Dry Objective

Any microscope objective designed for use without liquid between the cover glass and the objective or, in the case of metallurgical objectives, in the space between objective and specimen.

Dry Permeability

In casting, the property of a molded mass of sand, bonded or unbonded, dried at -100°C to 110°C (-220°F to 230°F), and cooled to room temperature, which allows the transfer of gases resulting during the pouring of molten metal into a mold.

Dry Sand Casting

The process in which the sand molds are dried at above 100°C (212°F) before use.

Dry Sand Mold

A casting mold made of sand and then dried at 100°C (212°F) or above before being used. It is in contrast with *green sand mold*.

Dry Sliding Wear

Sliding wear in which there is no intentional lubricant or moisture introduced into the contact area. See also *unlubricated sliding*.

Dry Strength (Adhesives)

The strength of an adhesive joint determined immediately after drying under specified conditions or after a period of conditioning in the standard laboratory atmosphere. See also *wet strength*.

Dry Strength (Casting)

The maximum strength of a molded sand specimen that has been thoroughly dried at -100°C to 110°C (-220°F to 230°F) and cooled to room temperature. It is also known as dry bond strength.

Dry Tack

The property of certain adhesives, particularly nonvulcanizing rubber adhesives, to adhere on contact to themselves at a stage in the evaporation of volatile constituents, even though they seem dry to the touch. It is the synonym for aggressive tack.

Dry Winding

In composites fabrication, filament winding using preimpregnated roving, as differentiated from wet winding, in which unimpregnated roving is pulled through a resin bath just before being wound onto a mandrel. See also *wet winding*.

Dry-Bulb Temperature

The temperature of the air as indicated by an accurate thermometer, corrected for radiation if significant.

Dry-Film lubrication

Lubrication that involves the application of a thin film of solid lubricant to the surface or surfaces to be lubricated.

Drying

Removal, by evaporation, of uncombined water or other volatile substances from a ceramic raw material or product, usually expedited by low-temperature heating.

Drying Oils

Vegetable oils that are easily oxidized by exposure to air and thus suitable for producing a film in paints and varnishes, known as *paint oils*. The use of drying oils as the sole or main binder in alkyd coatings is steadily decreasing with the advent of water-based latex paints. Currently, it is limited to solvent-thinned exterior house paints and some metal paints. The oils are also used in oleoresinous varnishes and in the manufacture of synthetic resins for coating binders, epoxy ester resins, and oil-modified urethane resins. Small amounts are used in printing inks, linoleum, putty and caulking compounds, core oils, and hardboard. The best drying oils are those that contain the higher proportions of unsaturated acids, in which oxidation causes polymerization of the molecules. The drying of an oleoresinous varnish takes place in two stages. First, the reducer or solvent evaporates, leaving a continuous film composed of gums and drying oil. The drying oil is then oxidized by exposure, leaving a tough, hard skin. This oxidation is hastened by driers, but the drying oil itself is responsible for the film. The drying power of oils is measured by their *iodine value*, as their power of absorbing oxygen from the air is directly proportional to their power of absorbing iodine. Drying oils have typical iodine values about 140, semidry oils above 120, and nondrying oils below 120. Linseed oil is the most common of the drying oils, though tung oil and oiticica oil are faster in drying action. Linseed oil alone will take about 7 days to dry, but can be quickened to a few hours by the addition of driers. Linseed oil and other oils may be altered chemically to increase the drying power.

Conjugated oils are oils that have been altered catalytically by nickel, platinum, palladium, or carbon to give conjugated double bonds in place of isolated double bonds in the molecules of the fatty acids. The iodine value is 180, and the drying time is greatly reduced.

D

Castor oil, which is for drying properties, is dehydrated to form a good drying oil. Other methods are used to alter oils to increase the drying power, notably polymerization of the linoleic and some other acids in the oils; or oils may be fractionated and rebled to increase the percentage of acids that produce drying qualities.

Drying Temperature

The temperature to which an adhesive or an adherend, an adhesive in an assembly, or the assembly itself is subjected to dry the adhesive. The temperature attained by the adhesive in the process of drying (adhesive drying temperature) may differ from the temperature of the atmosphere surrounding the assembly (assembly drying temperature). See also *curing temperature* and *setting temperature*.

Drying Time

The period of time during which an adhesive or an adherend or an assembly is allowed to dry with or without the application of heat or pressure, or both. See also *curing time*, *joint conditioning time*, and *setting time*.

Dry-Running

In seals, running without liquid present at the seal surface.

Dry-Sand Rubber Wheel Test

In wear testing, the term used to describe a standard abrasive wear testing method in which a stream of dry quartz sand is passed between a rotating rubber wheel and a stationary test coupon that is held against it under specified normal force.

DSC

See *differential scanning calorimetry*.

DTA

See *differential thermal analysis*.

DTUL

See *deflection temperature under load*.

Dual-Metal Centrifugal Casting

Centrifugal castings produced by pouring a different metal into the rotating mold after the first metal poured has solidified. This is also referred to as *bimetal casting*.

Dual-Phase Steels

A new class of high-strength low-alloy steels characterized by a tensile strength value of approximately 550 MPa (80 ksi) and by a microstructure consisting of about 20% hard martensite particles dispersed in a soft ductile ferrite matrix. The term dual phase refers to the predominance in the microstructure of two phases, ferrite and martensite. However, small amounts of other phases, such as bainite, pearlite, or retained austenite, may also be present.

Duck

A strong, heavy cotton fabric employed for sails, awnings, tents, heavy bags, shoe uppers, machine coverings, and where a heavy and durable fabric is needed. It is woven plain, but with two threads together in the warp. It is made in various weights and is designated by the weight in ounces per running yard 22 in. (0.6 m) wide. It is marketed unbleached, bleached, or dyed in colors, and there are about 30 specific types with name designations usually for particular uses such as *sailcloth*. When woven with a colored stripe, it is called *awning dock*. *Russian duck* is a fine variety of *linen duck*. Large quantities of cotton duck are used for making laminated plastics and for plastics-coated fabrics and are then simply designated by the weight. *Belt duck*, for impregnated conveyor and transmission belts, is made in loosely woven, soft ducks and in hard-woven, fine-yarn hard fabric. *Conveyor belting* for foodstuff plants is usually a plastic fabric for cleanliness.

Hose duck, for rubber hose, is a soft-woven fabric of plied yarns. Canvas is duck of more open weave. The term is used loosely in the United States to designate heavy duck used for tarpaulins, bags, sails, and tents. But more properly, it is a heavy duck of square mesh weave more permeable than ordinary duck, such as the canvas used for paintings and for embroidery work. The word *duck* is from the Flemish *doeck*, meaning cloth, originally a heavy linen fabric. The word canvas is from the Latin *cannabis*, originally a coarse, heavy hempen cloth for tents.

Drill is a stout, twill cotton fabric used for linings and where a strong fabric lighter than duck is required. It differs from duck also in that it has a warp-flush weave that brings more warp than filling to the face of the cloth. It comes unbleached, bleached, or piece dyed, or it may be yarn dyed. It is made in various weights and is designated in ounces per yard, which is the same as duck. Tan-colored drill is called *khaki*. *Denim* is a heavy, twill-woven, warp-flush fabric usually lighter in weight than drill. The warp is yarn dyed. The filling is made with one black and one white yarn. It is much used for workers' clothing, and the lightweights for sportswear are called *jeans*. Denim is also used industrially where a tough fabric is needed. *Art denim*, in plain colors or woven with small figures, is used for upholstery.

Ductile Crack Propagation

Slow crack propagation that is accompanied by noticeable *plastic deformation* and requires energy to be supplied from outside the body. This is in contrast with *brittle crack propagation*.

Ductile Erosion Behavior

Erosion behavior having characteristic properties (i.e., considerable *plastic deformation*) that can be associated with *ductile fracture* of the exposed solid surface. A characteristic ripple pattern forms on the exposed surface at low values of angle of attack. This is in contrast with *brittle erosion behavior*.

Ductile Fracture

Fracture characterized by tearing of metal accompanied by appreciable gross plastic deformation and expenditure of considerable energy. This is in contrast with *brittle fracture*.

Ductile Iron

A *cast iron* that has been treated while molten with an element such as magnesium or cerium to induce the formation of free graphite as

nodules or spherulites, which imparts a measurable degree of ductility to the cast metal. Ductile irons typically contain 3.0%–4.0% C, 1.8%–2.8% Si, 0.1%–1.0% Mn, 0.01%–0.1% P, and 0.01%–0.03% S. It is also known as nodular cast iron, spherulitic graphite cast iron, and spheroidal graphite iron.

Ductile iron is a graphite containing ferrous metal in which the graphite appears as rounded particles or spheroids rather than the usual plates, flakes, or clumps typical of other graphite ferrous metals.

In spherical form, the graphite exerts a minor influence on the properties of the steellike matrix because in that form the graphite-to-metal contact area is at a minimum. It is relatively economical to produce and has found applications in many industries.

Ductile iron is similar to other high-carbon, high-silicon alloys with respect to corrosion resistance, sliding wear, and machinability except insofar as the shape of the graphite alters these characteristics. The spheroidal form of the graphite, with lower surface area, alters corrosion resistance where the graphite is cathodic to the surrounding material. In comparison, with flake graphite iron, greater power will be required to remove metal in machining, while in metal-to-metal contact, the greater toughness resists removal of metal particles and therefore increases resistance to certain types of wear.

The spheroidal graphite irons have very good machining characteristics by virtue of their contained graphite and compare favorably with other materials at equivalent hardnesses and strengths. The soft annealed grade provides a strong, tough material that can be turned at very high speeds and feeds. Maximum turning speeds of well over 400 surface ft/min are attainable in this great. The cutting speed is, however, determined by the microstructure and maximum turning speed of the pearlitic grade reduced to about 150 surface ft/min and of the hardest oil-quenched grade to 100 surface ft/min. The chip produced in machining operations tends to be long and continuous, which complicates such operations as deep-hole drilling and internal broaching and reaming. For fast metal removal in these operations, special tool configurations are required to provide access for chip removal. Cutting fluids are recommended for all machining operations and, of course, production machining requires the use of carbide-tipped tools.

Welding

It is possible and practical to weld the spheroidal graphite irons by several welding processes. Most commonly used are the metallic arc and oxyacetylene processes. Due to the high carbon content and consequently high hardenability, the material must be handled very carefully to prevent excessive FeC from forming at the welding temperature. If maximum ductility and machinability are desired in the heat-affected zone, the welding operation should be followed by annealing. Filler rods, which undergo no phase changes, such as a 60% Ni–40% Fe rods, are the easiest and most practical to use. The operation requires the lowest practical input of amperage in the use of welding techniques that prevent overheating of the base metal in any location. The annealed grade, containing little or no combined carbon (to harden on cooling), is the grade on which welding is most easily performed.

Brazing

The joining of ductile iron castings to similar or dissimilar metals can be accomplished with silver or copper brazing filler metals, usually without resorting to special techniques in preparing the surfaces to be brazed. Overlay with hard surfacing alloys also presents no special problems.

Available Forms

Because its normal composition makes it eminently suited, ductile iron is essentially a casting alloy. In this condition, a wide variety of control is available on its properties through composition in heat treatment. Ferritic castings may be processed further by hot bending to shapes too difficult to cast conveniently. Tubular shapes may be formed by centrifugal casting and by the hot extruding of billets. The forging, rolling, extruding, and stamping processes may be used to produce bars, shafts, pipe, plate, angles, beams, gear blanks, etc., in order to utilize the good machinability and produced by explosive corrosion resistance of this high-silicon, high-carbon material. Certain shapes have been produced by explosive forming.

Applications

The incorporation into one material of high strength in all section sizes, excellent castability, wear resistance, machinability, and relatively simple control of properties suggests that such material would find application in many different industries and applications. It is lighter than nongraphic ferrous metals and, with its high strengths and good castability, permits the design of thin-section, lighter-weight machine components. The largest outages are used in automobile and diesel engines for crankshafts, rocker arms, and other engine and clutch components; in farm equipment and tractors for gears, sprockets, brackets, transmission casings, housings, and many structural components; in earthmoving machinery for the wheels, gears, and rope drums; and in heavy machinery for load-carrying components requiring good wear, easy machining, high strength, and antideflexion properties. Other applications include fluid-handling devices such as valves and fittings; paper-mill machinery, roles, role heads, and gears; and steel mill rolls and mill equipment; as well as many others in a variety of industries.

Ductility

The capability of a metal to undergo plastic deformation during tensile loading. It is measured in the tensile test as the percentage reduction in cross-sectional area at the point of failure so material that can be drawn to a point before failing in tension has 100% ductility.

Ductility Transition, Ductile-to-Brittle Transition

(1) The temperature at which steel changes between ductile and brittle fractures about modes. (2) Some arbitrary level of energy absorption measured by impact testing. The actual energy level to be exceeded and, usually, temperature limitations are specified for this with most impact testing; the actual results do not provide a quantitative guide to surface performance. See *brittle fracture*.

Dullness

A lack of pultruded surface gloss or shine in plastic parts. This can be caused by insufficient cure locally or in large areas, resulting in the dull band created on a pultruded part within the die when the pultrusion process is interrupted briefly.

Dummy Block

In *extrusion*, a thick unattached disk placed between the ram and the billet to prevent overheating of the ram.

D

Dummy Cathode

(1) A *cathode*, usually corrugated to give variable current densities, that is plated at low current densities to preferentially remove impurities from a plating solution. (2) A substitute cathode that is used during adjustment of operating conditions.

Dummying

(1) An initial rough shaping in open dies prior to die forging. (2) Plating with *dummy cathodes*.

Dump Test

A test of malleability in which a columnar specimen is compressed longitudinally. It is typically applied to bar for rivets or bolts.

Duoplasmatron

A type of ion source in which a plasma created by an arc discharge is confined and compressed by a nonuniform magnetic field.

Duplex Alloys

Bearing alloys consisting of two phases, one much softer than the other.

Duplex Coating

See *composite plate*.

Duplex Grain Size

The simultaneous presence of two grain sizes in substantial amounts, with one grain size appreciably larger than the others. This is also termed as mixed grain size.

Duplex Microstructure

A two-phase structure.

Duplex Stainless Steels

(1) Stainless steels having a fine-grained mixed microstructure of ferrite and austenite with a composition centered around 26 Cr–6.5 Ni. The corrosion resistance of duplex stainless steels is like that of austenitic stainless steels. However, duplex stainless steels possess higher tensile and yield strengths and improve resistance to stress-corrosion cracking than their austenitic counterparts. (2) Grades of stainless steel containing high levels of chromium with nickel and, usually, small editions of molybdenum, for example, 22% chromium, 6% nickel, and 3% molybdenum. With further additions, for example, copper and tungsten, the steel may be termed superduplex: Tight control of composition and manufacturing variables produces a microstructure of austenite and ferrite in a specific ratio and distribution. These steels offer excellent corrosion resistance in certain circumstances. See also *steel* and *stainless steel*.

Duplexing

Any two-furnace melting or refining process. This is also called duplex melting or duplex processing.

Duplicate Measurement

A second measurement made on the same (or identical) sample material to assist in the evaluation of measurement variance.

Duplicate Sample

A second sample randomly selected from a population to assist in the evaluation of sample variance.

Duplicating

In machining and grinding, reproducing a form from a master with an appropriate type of machine tool, utilizing a suitable tracer or program-controlled mechanism.

Duralumin (Obsolete)

A term frequently applied to the class of age-hardenable aluminum–copper alloys containing manganese, magnesium, or silicon. This is also called Dural. It is in the proprietary range of aluminum alloys and sometimes used as a generic term for any aluminum alloy that can be straightened by heat treatment. See *precipitation hardening*.

Durometer Reading

An index that is used for ranking the relative hardness of elastomers. The durometer hardness test involves forcing a 30° tapered indenter into the surface of the specimen using calibrated loading springs. A dial gauge indicates the depth of penetration in durometer numbers, which are directly proportional to the load on the spring.

Durville Process

A casting process that allows rigid attachment of the mold in an inverted position above the crucible. The melt is poured by tilting the entire assembly, causing the metal to flow along a connecting *launder* and down the side of the mold. This minimizes contact with air and reduces the risk of dross and entrapment.

Dust

Specifically, a superfine metal powder having predominantly submicron-sized particles.

Dusting

(1) A phenomenon usually affecting carbon-based electrical motor brushes or other current-carrying contacts, wherein at low relative humidity or high applied current density, a powdery *dust* is produced during operation. (2) Applying a powder, such as sulfur to molten magnesium or graphite to a mold surface.

Duty

This specification giving the load, ambient temperature, and speed under which surfaces are required to move.

Duty Cycle

For electric welding equipment, the percentage of time that current flows during a specified period. In arc welding, the specified period is 10 min.

Duty Parameter

See *capacity number*.

Dwarf Width

A condition in which the crosswise (of the direction of pultrusion) dimension of a flat surface of a part is less than that which the die would normally yield for a particular plastic or composite. The condition is usually caused by a partial blockage of the pultrusion die cavity caused by buildup or particles of the composite adhering to the cavity surface. This condition is commonly called a lost edge, when the flat surface has a free edge that is altered by the buildup.

Dwell

(1) In forming plastics and composites, a pause in the application of pressure or temperature to a mold, made just before it is completely closed, to allow the escape of gas from the molding material. In filament winding, it is the time that the traverse mechanism is stationary while the mandrel continues to rotate to the appropriate point for the traverse to begin a new pass. In a standard autoclave cure cycle, it is an intermediate step in which the resin matrix is held at a temperature below the cure temperature for a specified period of time sufficient to produce a desired degree of staging. Used primarily to control resin flow. (2) The term is commonly used in the context of thermal fatigue testing where a load is applied, sustained for a period of hours or days, the dwell period, and then removed; this cycle is being repeated a number of times. The specimen is maintained at a high temperature during the dwell period so it sees not only a fatigue cycle but also suffers considerable creep.

Dwell Mark

A fracture surface marking that resembles a pronounced ripple mark, the presence of which indicates that the fracture paused at the location of the dwell mark for some indeterminable length of time. This is also known as arrest mark.

Dwell Time

In powder metallurgy, the time period during which maximum pressure is applied to a compact in cold pressing or hot pressing.

Dye Penetrant (Examination)

A liquid containing a dye capable of entering narrow cracks. Components suspected of containing cracks are immersed in, or swabbed or sprayed with, the penetrant. After the component has been wiped clean, any penetrant retained in a crack will seep out indicating the defect. Some dyes are fluorescent in the component when it is viewed, after application of the dye, under ultraviolet light. Sensitivity is usually improved by a developer, a powder, or quick-drying coating, applied immediately after wiping off excess penetrant, which absorbs and acts as a contrasting background for the dye.

Dyestuffs

Materials, also called *colorants*, used to color textiles, paper, leather, wood, or other products. They may be either natural or artificial. Many chemicals will stain and color other materials, but a product is not considered a dye unless it will impart a distinct color of some permanence to textiles. The natural dyestuffs may be mineral, animal, or vegetable, but the artificial dyes are derived mainly from coal-tar bases. Almost all naturally extracted dyes have been replaced by synthetic counterparts for commercial use. *Mineral dyes*

now include ocher, chrome yellow, and Prussian blue. *Vegetable dyes* may be water solutions of woods, barks, leaves, fruits, or flowers. The buff and brown textile colors of early New England were made by boiling fresh green butternuts in water, while a dark-red dye was made by boiling the common red beet in water.

Synthetic dyes are mostly coal-tar or aniline colors. They are more intense, brighter, faster, and generally cheaper than natural dyestuffs. The dyes are complex chemicals, but they usually contain characteristic groups of atoms so that the color or change in color can be predicted.

Some of the synthetic dyes will color animal fibers well and not vegetable fibers, or vice versa, while some will color all fibers. As a result, it is possible to divide the bulk of the dyes into six classes, including *azoic dyes*. The *direct dyes* can be dyed directly, while others require a mordant. Some are permanent, or fast, while others are water soluble and will fade when the fabric is washed, where some may not be lightfast and will fade when exposed to light. Direct dyes usually have a weak OH bond between the nitrogen in the dye and the fiber, usually cotton. In *reactive dyes*, the dye reacts with the fiber to produce both in OH and in oxygen linkage, which is the chlorine combining with the hydroxyl to form a strongly ether linkage. Such dyes are fast and very brilliant and are used for cotton, rayon, and nylon. *Acid dyes* contain a carboxylic or sulfuric acid group and operate best in an acid bath. They are used for drying protein fibers, such as wool, silk, and nylon, and sometimes for leather and paper. They are usually azo, *triarylmethane*, or anthraquinone complexes. Basic dyes are commonly amino and substituted amino compounds, such as *triarylmethane* or *xanthenes*. They are used for dyeing cotton with a mordant. *Vat dyes* are insoluble and are applied in the soluble colorless form and then reduced or oxidized to color. They usually have an anthraquinone or *indanthrene* structure and are solubilized by the reducing agent, a hydroxyl group, OH, diffusing into the fiber where it is fixed; the best-known example is *indigo*, the dye synonymous with the color of blue jeans, which has become one of the most important colorants because of the popularity of *denim* garments. Originally derived from plants, synthetic indigo dye now dominates the market. Synthesis, first commercialized by BASF of Germany more than 100 years ago, uses aniline formaldehyde and sodium cyanide as the raw materials. The process generates toxic wastewater. A biosynthesis process of Genecor International, Inc., however, is said to be environmentally benign. Pioneered by Amgen, Inc., and the University of Texas, it uses no petrochemical feedstocks, and biomass is the only waste product.

Color carriers, used to aid adherence of dyes to synthetic fibers, are usually chemicals that act as swelling agents to open the fiber structure, such as phenylphenol, benzoic acid, or dichlorobenzoic acid.

Dynamic

Moving or having high velocity. This is frequently used with high-strain-rate ($<0.1 \text{ s}^{-1}$) testing of metal specimens. This is in contrast with *static*.

Dynamic Creep

Creep that occurs under conditions of fluctuating load or fluctuating temperature.

Dynamic Electrode Force

The force given in newtons (pounds force) between the electrodes during the actual welding cycle in making spot, seam, or projection welds by resistance welding.

D**Dynamic Friction**

See *kinetic friction*.

Dynamic Hot Pressing

In powder metallurgy, a method of applying a vibrational load to the punches or die during hot pressing. See also *hot pressing* and *static hot pressing*.

Dynamic Load

An imposed force that is in motion, that is, one that may vary in magnitude, sense, and direction.

Dynamic Mechanical Measurement

A technique in which either the modulus and/or damping of a substance under oscillatory load or displacement is measured as a function of temperature, frequency, or time, or a combination thereof.

Dynamic Modulus

The ratio of stress to strain under cyclic conditions (calculated from data obtained from either free or forced vibration tests, in shear, compression, or tension).

Dynamic Seal

A seal that has rotating, oscillating, or reciprocating motion between its components, as opposed to stationery-type seal such as a gasket.

Dynamic Viscosity

See *viscosity*.

Dysprosium

A metallic element, in the rare earth group.

E

The elastic modulus, the ratio of extension to original length. See *tensile test*.

Ears/Earing

(1) The undesirable deeply scalloped edge of deep-drawn components due to preferred orientation. A typical cup-shaped component suffering from the defect will have four equally spaced deep scallops separating the ears that are aligned along and transverse to the rolling direction of the original sheet. (2) The formation of ears or scalloped edges around the top of a drawn shell, resulting from directional differences in the plastic-working properties of rolled metal, with, across, or at angles to the direction of rolling.

Earth

The nonpowered return path of an electrical circuit. It may not be via the soil.

Earthenware

A glazed or unglazed nonvitreous clay-based ceramic *whiteware*.

Eccentric

(1) Not concentric. Most to be produced by piercing and similar processes is significantly eccentric. (2) A disc set on a shaft with its center offset from the center of the shaft. (3) The offset portion of the driveshaft that governs the stroke or distance the crosshead moves on a mechanical or manual shear.

Eccentric Gear

A main press-drive gear with an eccentric (s) as an integral part. The unit rotates about a common shaft, with the eccentric transmitting the rotary motion of the gear into the vertical motion of the slide through a connection.

Eccentric Press

A *mechanical press* in which an eccentric, instead of a crankshaft, is used to move the *slide*.

Eccentricity

In *journal bearings*, the radial displacement of the journal center from the center of the bearing liner.

Eccentricity Ratio

In a bearing, the ratio of the eccentricity to the radial clearance.

ECM

An abbreviation for *electrochemical machining*.

Eddy Current Testing

A form of nondestructive testing in which eddy currents are induced in the component under test. The basic principle is that the probe that induces the eddy current moves relative to the component, or vice versa. Any changes in the current induced in the component are detected by the probe and transmitted to the monitoring equipment to indicate the location and size of the effects.

Edge Cracks

Shallow cracks in hardened steel containing high residual surface stresses, produced by etching in an embrittling acid.

Edge Dislocation

A line defect with its Burger's Vector perpendicular to the line of dislocation. See *dislocation*.

Edge Distance

The distance from the edge of a bearing test specimen to the center of the hole in the direction of applied force. See also *bearing test*.

Edge Distance Ratio

In a *bearing test*, the distance from the center of the bearing hole to the edge of a specimen in the direction of the principal stress, divided by the diameter of the hole.

Edge Effect (Thermal Spraying)

Loosening of the bond between the sprayed material and the base material at the edges, due to stresses set up in cooling.

Edge Joint (Adhesive Bonding)

A joint made by bonding the edge faces of two adherends.

Edge Joint (Welding)

A joint made between the edges of sheet or plate components particularly when they meet at an acute angle, usually less than 30°.

Edge Preparation

Surface preparation on the edge of a member for welding.

E

Edge Stability

An indicator of strength in a green powder metallurgy compact, as may be determined by tumbling in a drum. See also *drum test*.

Edge Strain

Transverse strain lines or Lüders lines ranging from 25 to 300 mm (1–12 in.) in the edges of cold rolled steel sheet or strip. See also *Lüders lines*.

Edge Strength

The resistance of the sharp edges of a powder metallurgy compact against abrasion, as may be determined by tumbling in a drum. See also *drum test*.

Edge Tool

A tool with one or more sharpened cutting edges.

Edge Weld

A weld in an *edge joint*.

Edge/Edging Rolls

Rolls that control the quality, dimensions, and shape of plate being rolled.

Edge-Flange Weld

A flange weld with two members flanged to the location of welding.

Edger (Edging Impression)

The portion of a die impression that distributes metal during forging into areas where it is most needed in order to facilitate filling the cavities of subsequent impressions to be used in the forging sequence. See also *fuller (fullering impression)*.

Edge-Trailing Technique

In metallography, a unidirectional motion perpendicular to and toward one edge of the specimen during abrasion or polishing used to improve edge retention.

Edging

(1) In sheet metal forming, reducing the flange radius by retracting the forming punch by a small amount after the stroke but before the release of the pressure. (2) In rolling, the working of metal in which the axis of the roll is parallel to the thickness dimension. It is also called edge rolling. (3) The forging operation of working a bar between contoured and dies while turning it 90° between blows to produce a varying rectangular cross-section. (4) In a forging, removing flash that is directed upward between dies, usually accomplished using a lathe.

EDM

Abbreviation for *electrical discharge machining*.

Effective Atomic Number

For an element, the number of protons in the nucleus of an atom. For mixtures, an effective atomic number can be calculated to represent a single element that would have attenuation properties identical to those of the mixture.

Effective Crack Size (α_e)

The *physical crack size* augmented for the effects of crack-tip plastic deformation. Sometimes, the effective crack size is calculated from a measured value of a physical crack size plus a calculated value of a plastic-zone adjustment. A preferred method for calculation of effective crack size compares compliance from the secant of a load-deflection trace with the elastic compliance from a calibration for the type of specimen.

Effective Draw

The maximum limits of forming depth that can be achieved with a multiple-action press, sometimes called maximum draw or maximum depth of draw.

Effective Leakage Area

The orifice flow area that will result in the same calculated flow for a given pressure drop as is measured for the seal in question. This concept is useful when comparing the leakage performance of seals of different sizes and designs, and of CEOs operating under different conditions.

Effective Length of Weld

The length of weld throughout which the correctly proportional cross-section exists. In a curve weld, it is measured along the axis of the weld.

Effective Modulus

The elastic modulus in circumstances where it is time-dependent or nonlinear. See also *secant modulus* and *tangent modulus*.

Effective Rake

The angle between a plane containing a tooth face and the axial plane through the tooth point as measured in the direction of chip flow through the tooth point. Thus, it is the rake resulting from both the cutter configuration and direction of chip flow.

Effective Throat

The minimum distance from the root of a weld to its face. See also *joint penetration*.

Effective Yield Strength

An assumed value of uniaxial yield strength that represents the influence of plastic yielding on fracture test parameters.

E-Glass

A family of glasses with a calcium aluminoborosilicate composition and a maximum alkali content of 2.0%. A general purpose fiber that

is most often used in reinforced plastics, and is suitable for electrical laminates because of its high resistivity. It is also called electric glass. See also *glass fiber*.

Eight-Harness Satin

A type of fabric weave. The fabric has a seven-by-one weave pattern in which a filling thread floats over seven warp threads and then under one. Like the crowfoot weave, it looks different on one side than on the other. This weave is more pliable than any of the others and is especially adaptable to forming around compound curves, such as on radomes.

Ejection

Removal of a powder metallurgy compact after completion of pressing, whereby the compact is pushed through the die cavity by one of the punches. Also called *knockout*.

Ejection Mark

A surface mark on a plastic part caused by the ejector pin when it pushes the part out of the molded cavity.

Ejector

A device mounted in such a way that it removes or assists in removing a focused part from a die.

Ejector Half

The movable half of a die-casting die containing the ejector pins.

Ejector Punch

See *knockout punch*.

Ejector Rod

A rod used to push out a formed piece.

Elastic after Effect

The elastic strain that develops with time in a component subject to a steady stress below its elastic limit. Compared with the immediately observed strain, it is very small. After removal of the stress, a similar small amount of strain remains but disappears with time.

Elastic Calibration Device

A device for use in verifying the load readings of a testing machine consisting of an elastic member(s) to which loads may be applied, combined with a mechanism or device for indicating the magnitude for a quantity proportional to the magnitude of deformation under load.

Elastic Compliance

A condition under which two bodies in contact, which are subjected to a force, undergo small elastic displacement without slip.

Elastic Constants

The factors of proportionality that relate elastic displacement of a material to applied forces. See also *bulk modulus of elasticity*, *modulus of elasticity*, *Poisson's ratio*, and *shear modulus*.

Elastic constants are the Tensile Elastic Modulus (Young's modulus) (symbol E), Compression Modulus (K), Shear Modulus (G), and Poisson's Ratio (δ).

Elastic Constraint

See *constraint*.

Elastic Deformation

A change in dimensions directly proportional to and in phase with an increase or decrease in applied force.

Elastic Electron Scatter

The scatter of electrons by an object without loss of energy, usually in interaction between electrons and atoms.

Elastic Energy

The amount of energy required to deform a material within the elastic range of behavior, neglecting small heat losses due to internal friction. The energy absorbed by a specimen per unit volume of material contained within the gauge length being tested. It is determined by measuring the area under the stress-strain curve up to a specified elastic strain. See also *modulus of resilience* and *strain energy*.

Elastic Hysteresis

The phenomenon whereby the stress-strain curves on loading and unloading do not coincide other than at maximum and minimum stress. It reflects the energy consumed in the elastic strain process and is a consequence of the elastic after effect. See *tensile test*. More appropriately termed *mechanical hysteresis*.

Elastic Limit

The maximum stress that a material is capable of sustaining without any permanent strain (deformation) remaining upon complete release of the stress. A material is said to have passed its elastic limit when the load is sufficient to initiate plastic, or nonrecoverable, deformation. See also *proportional limit*.

Elastic Modulus

The ratio of stress to strain in the elastic range. See *tensile test*. Same as *modulus of elasticity*.

Elastic Ratio

Yield point divided by *tensile strength*.

Elastic Recovery

(1) The fraction of a given deformation that behaves elastically. A perfectly elastic material has an elastic recovery of 1; a perfectly

E

plastic material has an elastic recovery of zero. (2) In hardness testing, the shortening of the original dimensions of the indentation upon release of the applied load.

Elastic Resilience

The amount of energy absorbed in stressing a material up to the elastic limit; or the amount of energy that can be recovered when stress is released from the elastic limit.

Elastic Scattering

Collisions between particles that are totally described by conservation of energy and momentum. Contrast with *inelastic scattering*.

Elastic Strain

See *elastic deformation*.

Elastic Strain Energy

The energy expended by the action of external forces in deforming a body elastically. Essentially, all the work performed during elastic deformation is stored as elastic energy, and this energy is recovered upon release of the applied force.

Elastic True Strain (ϵ_e)

Elastic component of the *true strain*.

Elastic Waves

Mechanical vibrations in an elastic medium.

Elasticity

The property of a material by virtue of which deformation caused by stress disappears upon removal of the stress. A perfectly elastic body completely recovers its original shape and dimensions after release of stress.

Elastohydrodynamic Lubrication

A condition of lubrication in which the friction and film thickness between two bodies in relative motion are determined by the elastic properties of the bodies, in combination with the viscous properties of the lubricant at the prevailing pressure, temperature, and rate of shear. See also *boundary lubrication*, *plastohydrodynamic lubrication*, and *thin-film lubrication*.

Elastomers

Elastomers and rubber are differentiated from polymers by the mechanical property of returning to their original shape after being stretched to several times their length. The rubber industry differentiates between the terms *elastomer* and *rubber* on the basis of how long a deformed material sample requires to return to its approximate original size after a deforming force is removed, and on its extent of recovery. The American Society for Testing and Materials (ASTM) defines an elastomer as “a polymeric material which at room temperature can be stretched to at least twice its original length and upon

immediate release of the stress will return quickly to approximately its original length.” ASTM D 1566 is more specific and quantitative in defining rubber as “a material that is capable of recovering from large deformations quickly and forcibly ... (and which), and its modified state, free of diluents, retracts within one minute to less than 1.5 times its original length after being stretched at room temperature to twice its length and held for one minute before release.”

The major distinguishing characteristic of elastomers is their great extensibility and high-energy storing capacity. Unlike many metals, for example, which cannot be strained more than a fraction of 1% without exceeding their elastic limit, elastomers of usable elongation is up to several hundred percent. Also, because of their capacity for storing energy, even after they are strained several hundred percent, virtually total recovery is achieved.

Before World War II, almost all rubber was natural. During the war, synthetic rubbers began to replace the scarce natural rubber, and since that time production of synthetics has increased and until now their use far surpasses that of natural rubber. There are thousands of different elastomer compounds. Not only are there many different classes of elastomers, but individual types can be modified with a variety of additives, fillers, and reinforcements. In addition, curing temperatures, pressures, and processing methods can be varied to produce elastomers tailored to the needs of specific applications.

Today, the term *rubber* means any material capable of extreme deformability, with more or less complete recovery upon removal of the deforming force. Synthetic materials such as neoprene, nitrile, styrene-butadiene (SBR), sometimes also called Buna S, and GR-S and butadiene rubber are now grouped with natural rubber. These materials serve engineering needs and fields dealing with shock absorption, noise and vibration control, sealing, corrosion protection, abrasion protection, friction production, electrical and thermal insulation, waterproofing, confining other materials, and load bearing.

Of all the available choices, SBR dominates the field, accounting for approximately one-half of all rubber—natural and synthetic—use in the United States. The demand for SBR has been responsible for the building of a massive production capability for this material. More than half of SBR production goes into passenger-car tires in the United States. Natural rubber is used almost exclusively in more demanding areas such as truck, bus, aircraft, and off-highway tires.

In the raw-material or crude stage, elastomers are thermoplastic. There are roughly 20 major classes of elastomers. For example, hard rubbers, which have the highest cross-linking of the elastomers, in many respects are similar to phenolics. In the unstretched state, elastomers are essentially amorphous because the polymers are randomly entangled and there is no special preferred geometrical pattern present. However, when stretched, the polymer chains tend to straighten and become aligned, thus increasing in crystallinity. This tendency to crystallize when stretched is related to the strength of an elastomer. Thus, as crystallinity increases strength also tends to increase (Table E.1). Neoprene, also known as chloroprene, has the distinction of being the first commercial synthetic rubber. It is chemically and structurally similar to natural rubber, and its mechanical properties are also similar. Its resistance to oils, chemicals, sunlight, weathering, aging, and ozone is outstanding. Also, it retains its properties at temperatures up to 121°C and is one of the few elastomers that does not support combustion, although it is consumed by fire. In addition, it has excellent resistance to permeability by gases, having about 1/4–1/10 the permeability of natural rubber, depending on the gas. Although it is slightly inferior to rubber in most mechanical properties, neoprene has superior resistance to compression set, particularly at elevated temperatures. It can be used for low-voltage insulation, but is relatively low in dielectric strength. Typical products made of chloroprene elastomers are heavy-duty conveyor belts,

TABLE E.1
Properties of Thermoplastic Elastomers

		Styrene Block			
ASTM Test	Property	Polyurethane	Co-Polyester	Copolymer	Olefin
Physical					
D792	Specific gravity	1.10–1.24	1.15–1.25	0.93–1.10	0.88–1.0

V belts, hose covers, footwear, break diaphragms, motor mounts, rolls, and gaskets. Butyl rubbers, also referred to as isobutylene–isoprene elastomers, are copolymers of isobutylene and 1%–3% isoprene. They are similar in many ways to natural rubber and are one of the lowest priced synthetics. They have excellent resistance to abrasion, tearing, and flexing. They are noted for low gas and air permeability (about 10 times better than natural rubber), and for this reason make a good material for tire inner tubes, hose, tubing, and diaphragms. Although butyls are non-oil-resistant, they have excellent resistance to sunlight and weathering, and generally have good chemical resistance. They also have good low-temperature flexibility and heat resistance up to around 149°C; however, they are not flame-resistant. They generally have lower mechanical properties such as tensile strength, resilience, abrasion resistance, and compression set, than the other elastomers. Because of their excellent dielectric strength, they are widely used for cable insulation, encapsulating compounds, and a variety of electrical applications. Other typical uses include weather stripping, coated fabrics, curtain wall gaskets, high-pressure steam hoses, machinery mounts, and seals for food jars and medicine bottles.

Isoprene is a synthetic natural rubber. It is processed like natural rubber and its properties are quite similar, although isoprene

has somewhat higher extensibility. Like natural rubber, its notable characteristics are low hysteresis, low heat buildup, and high tear resistance. It also has excellent flow characteristics, and is easily injection-molded. Its uses complement those of natural rubber, and its good electrical properties plus low moisture absorption make it suitable for electrical insulation. Polyacrylate elastomers are based on polymers of butyl or ethyl acrylate. They are low-volume use, specialty elastomers, chiefly used in parts involving oils (especially sulfur-bearing) at elevated temperatures of 149°C and even as high as 204°C. A major use is for automobile transmission seals. Other oil-resistant uses are gaskets and O rings. Mechanical properties such as tensile strength and resilience are low. Further, except for recent new formulations, they lose much of their flexibility below –23°C. The new grades extend low-temperature service to –40°C. Polyacrylates have only fair dielectric strength, which improves, however, at elevated temperatures.

Nitrile elastomers, or NBR rubbers, known originally as Buna N, are copolymers of acrylonitrile and butadiene. They are principally known for their outstanding resistance to oil and fuels at both normal and elevated temperatures. Their properties can be altered by varying the ratio of the two monomers.

Most commercial grades range from 20% to 50% acrylonitrile. Those at the high end of the range are used where maximum resistance to fuels and oils is required, such as in oil well parts and fuel hose. Low-acrylonitrile grades are used where good flexibility at low temperatures is of primary importance. Medium-range types, which are the most widely used, find applications between these extremes. Typical products are flexible couplings, printing blankets, rubber rollers, and washing machine parts. Nitriles as a group are low in most mechanical properties. Because they do not crystallize appreciably when stretched, their tensile strength is low, and resilience is roughly one-third to one-half that of natural rubber. Depending on acrylonitrile content, low-temperature brittleness occurs at from -26°C to -60°C . Their electrical insulation quality varies from fair to poor. Polybutadiene elastomers are notable for their low-temperature performance. With the exception of silicone, they have the lowest brittle or glass transition temperature, -73°C , of all the elastomers. They are also one of the most resilient, and have excellent abrasion resistance. However, resistance to chemicals, sunlight, weathering, and permeability by gases is poor. Some uses are shoe heels, soles, gaskets, and belting. They are also often used in blends with other rubbers to provide improvements in resilience, abrasion resistance, and low-temperature flexibility.

Polysulfide elastomer is rated highest in resistance to oil and gasoline. It also has excellent solvent resistance, extremely low gas permeability, and good aging characteristics. Thus, it is used for such products as oil and gasoline hoses, gaskets, washers, and diaphragms. Its major use is for equipment and parts in the coating production and application field. It is also widely applied in liquid form in sealants for the aircraft and marine industries. Its mechanical properties, including strength, compression set, and resilience, are poor. Although it is poor in flame resistance, it can be used in temperatures up to 121°C . Ethylene-propylene elastomers, or EPR rubber, are available as copolymers and terpolymers. They offer good resilience, flexing characteristics, compression-set resistance, and hysteresis resistance, along with excellent resistance to weathering, oxidation, and sunlight. Although fair to poor in oil resistance, their resistance to chemicals is good. Their maximum continuous surface temperature is around 177°C . Typical applications are electrical insulation, footwear, auto hose, and belts. Urethane elastomers are copolymers of diisocyanate with their polyester or polyether. Both are produced in solid gum form and viscous liquid. With tensile strengths above 34 MPa and some grades approaching 49 MPa, urethanes are the strongest available elastomers. They are also the hardest, and have extremely good abrasion resistance. Other notable properties are low compression set, and good aging characteristics and oil and fuel resistance. The maximum temperature for continuous use is under 93°C , and their brittle point ranges from -51°C to -68°C . Their largest field of application is for parts requiring high wear resistance or strength. Typical products are forklift truck wheels, airplane tail wheels, shoe heels, bumpers on earth-moving machinery, and typewriter damping pads. Chlorosulfonated polyethylene elastomer, commonly known as *Hypalon*, contains about one-third chlorine and 1%–2% sulfur. It can be used by itself or blended with other elastomers. *Hypalon* is noted for its excellent resistance to oxidation, sunlight, weathering, ozone, and many chemicals. Some grades are satisfactory for continuous service at temperatures up to 177°C . It has moderate oil resistance. It also has unlimited colorability. Its mechanical properties are good but not outstanding, although abrasion resistance is excellent. *Hypalon* is frequently used in blends to improve oxidation and ozone resistance. Typical uses are tank linings, high-temperature conveyor belts, shoe soles and heels, seals, gaskets, and spark plug boots. Epichlorohydrin elastomers are noted for their good resistance to oils, and excellent resistance to ozone, weathering, and intermediate heat. The homopolymer has extremely low permeability to gases. The copolymer has excellent resistance at low temperatures.

Both have low heat buildup, making them attractive for parts subjected to repeated shocks and vibrations. Fluorocarbon elastomers, fluorine-containing elastomers, like their plastic counterparts, are highest of all the elastomers in resistance to oxidation, chemicals, oils, solvents, and heat, in they are also the highest in price. They can be used continuously at a temperature of 127°C and do not support combustion. Their brittle temperature, however, is only -23°C . Their mechanical and electrical properties are only moderate. Unreinforced types have tensile strengths of less than 13 MPa and only fair resilience. Typical applications are brake seals, O rings, diaphragms, and hose. The phosphonitrile plastics and elastomers have high elasticity and high-temperature resistance. They are derived from chlorophosphonitrile, or phosphonitrilic chloride, are highly resistant to oils and solvents, and remain flexible and serviceable at temperatures from -57°C to 177°C .

Viton is a vinylidene fluoride hexafluoropropylene tetrafluoroethylene copolymer as well as *Fluorel* with extra high resistance to solvents, hydrocarbons, steam, and water.

Silicone elastomers are polymers composed basically of silicon and oxygen atoms. There are four major elastomer composition groups. In terms of application, silicone elastomers can be divided roughly into the following types: general-purpose, low-temperature, high-temperature, low-compression set, high-tensile, high-tear, fluid-resistant, and room-temperature vulcanizing. All silicone elastomers are high-performance, high-price materials. The general-purpose grades, however are competitive with some of the other specialty rubbers, and are less costly than the fluorocarbon elastomers. Silicone elastomers are the most stable group of all the elastomers. They are outstanding in resistance to high and low temperatures, oils, and chemicals. High-temperature grades have maximum continuous service temperatures up to 316°C ; low-temperature grades have glass transition temperatures of -118°C . Electrical properties, which are comparable to the best of the other elastomers, are maintained over a temperature range from -73°C to over 260°C . However, most grades have relatively poor mechanical properties. Tensile strength runs only around 8 MPa. However, grades have been developed with much improved strength, tear resistance, and compression set. Fluorosilicone elastomers have been developed that combine the outstanding characteristics of the fluorocarbons and silicones. However, they are expensive and require special precautions during processing. A unique characteristic of one of these elastomers is its relatively uniform modulus of elasticity over a wide temperature range and under a variety of conditions. Silicone elastomers are used extensively in products and components where high-performance is required. Typical uses are seals, gaskets, O rings, insulation for wire and cable, and encapsulation of electronic components.

Elastomeric Linings

Elastomeric lining materials are available in natural rubber, GR-S, butyl, neoprene, nitrile, and Hypalon synthetic rubbers as well as in polyvinyl chloride (PVC) and polyvinylidene chloride (**saran**) plastics and fluorocarbon rubbers. These basic materials, when formulated and processed into linings, are normally sold unapplied as heavy sheets at 4.7–6.4 mm thick.

Elastomeric linings are manufactured by plying up thin calendared films of 0.038–0.076 mm thickness to the full thickness of the lining.

They are applied in the soft and plastic uncured state to the base metal and are cured in place.

Natural Rubber

About 70% of the applied linings are estimated to be based on natural rubber. This is due to the fact that natural rubber can be formulated

in an extremely wide range of physical properties. Linings from natural rubber are classified as soft (sulfur content at 2%–3%), semi-hard (sulfur content at 15%–30%), and hard (sulfur content at 30%–45%). As the sulfur content is increased, general chemical resistance increases from good to excellent, but at the same time the lining also becomes harder and less flexible.

Linings from natural rubber are among the lowest in cost, and all natural rubber linings can be applied without difficulty. Even hard rubber can be used satisfactorily on large vessels if the vessel is designed in sections that are then bolted together and the joints covered with lap straps. With proper usage and suitable repair when damaged, they can be expected to give service for 12–15 years or more, which makes for a very low overall cost.

Natural rubber linings give excellent service for many water solutions of chemicals and can be used for practically all plating solutions (except chromium). Hard rubber linings will also withstand paraffenic oils, greases, and fats at moderate temperatures. The linings will not withstand the solvating action of aniline, benzene, carbon disulfide, carbon tetrachloride, and other chlorinated or halogenated hydrocarbons. They are not resistant to the chemical attack of the oxidizing acids, HNO_3 above 10% or H_2SO_4 acid above 50% at 71°C.

GR-S

With the exception of gum (nonfilled) rubber linings, GR-S can be used to duplicate practically all of the linings that are now made from natural rubber and for the same type of service.

Butyl Rubber

Butyl rubber linings are available in physical characteristics approaching those of the soft natural rubbers.

Butyl linings have a higher degree of general chemical resistance than natural rubber, and are suitable for weak oxidizing acids and for organic chemicals that deteriorate soft rubber linings over a long period of time (e.g., fats, greases, and soaps).

Butyl linings are suitable for use above 71°C and for continued use at 149°C as a lining material. These characteristics allow butyl use in tank trucks and railroad tank cars where hot solutions are to be transported, and where the empty car can be returned without fear of rupture of the lining by shock in cold climates. Also, butyl is used where the continual vibration and shock encountered in railroad hauling illuminates the semihard and hard rubbers that would normally be used for such solutions. HF_3 and ethylene chlorohydrin can be handled with butyl linings.

Neoprene

Neoprene linings have gained acclaim for their resistance to caustic solutions and are recommended for use with fluorides and phosphates. Flexible neoprene linings also have good resistance to a large group of chemicals such as all fatty acids, oils, greases, and aliphatic hydrocarbons; they are superior to butyl rubber in this respect. Such resistance enables the neoprene linings to give good service and chemical processes where mixtures of acids with kerosene, oils, or other organic materials are involved.

Because neoprene is more expensive than natural rubber, it is normally used only where it gives service superior to natural rubber. Neoprene linings are specifically used where flexibility is needed above 71°C.

Nitrile Rubber

Nitrile rubber linings, because of their relatively high cost, are used only with specific organic solvents, where organic solvents are used in conjunction with acids and other water-based corrosive systems and

where superior oil resistance is needed. The general chemical resistance of nitrile rubbers is only fair, but their resistance to oils is good.

Hypalon

Hypalon linings are flexible and are useful because of their resistance to heat as well as to oxidizing chemicals. Hypalon linings are especially suitable for use with hypochlorites and H_2SO_4 ; cold solutions of H_2SO_4 up to 90% exhibit very little attack upon Hypalon. It is probably the best lining available for hot solutions of H_2SO_4 below 50% concentration.

Polyvinyl Chloride (PVC)

PVC linings are available both in the flexible and rigid state. Flexible PVC is used almost exclusively where H_2CrO_3 solutions are involved in chromium plating, and where HNO_3 or mixtures of HNO_3 and HF acids are involved in the electropickling of stainless steels. No other linings are suitable for these operations. PVC linings are also suitable where mixtures of water solutions of corrosive chemicals with oils or specific organic solvents are involved.

Similar to PVC are the saran (polyvinylidene chloride) linings, which look like and are applied in much the same manner as PVC. They are good for use with HCl.

Application

Elastomeric linings are applied in much the same manner as wallpaper. In the application of rubber linings, it is important that the lining be applied when the rubber is uncured and is plastic and workable.

PVC and polyvinylidene chloride linings are applied similarly to rubber linings but they are not cured. There are applied with butt joints covered with a narrow sealing strip.

Uses

Elastomeric linings can be compounded to provide specific corrosion resistance for many applications and can be applied to almost any shape of equipment or surface under almost any set of conditions and at any location.

Those industries using the highest volume of linings include:

1. Chemical process industry, where practically every type of lining is utilized for a wide variety of chemicals
2. The steel and aluminum industries, where the linings are used in pickling and anodizing operations
3. In the automotive and appliance industries, for plating
4. In ordnance, where missile fuels are involved
5. The food processing industry, where specifically compounded linings are used in smaller volume.

Elastomeric Tooling

A tooling system that uses the thermal expansion of rubber materials to form reinforced plastic or composite parts during cure.

Electrical Ceramics

Electrical ceramics, like all other ceramics, consist of randomly oriented small crystallites, bonded together by either a glassy matrix or by close interlocking of one or several crystalline phases. The atomic structures of the crystalline and glassy phases determine the physical properties of the finished ceramic.

E

Raw Materials

Conventional raw materials for ceramic production are earthy, natural minerals, used in finely-ground form, such as clays, talc, feldspar, and flint. These are used for the production of electrical insulators, often carefully selected and refined from gross impurities by flotation or filtering processes. In many instances, these naturally occurring minerals are replaced by synthesized inorganic compounds, which are prepared from various oxides. This may be done by melting, recrystallizing, and grinding, or more frequently by high-temperature solid-state reactions.

These compounds may be composed of oxides of practically any metal, singly or in combination, or they may be refractory compounds such as carbides and silicides. The use of these inorganic synthetic raw materials has opened the field of likely ceramic compositions to practically infinite numbers, and the possibility of variation in physical and electrical properties is therefore equally staggering.

Fabrication Techniques

The compositions, which may consist of either finely ground minerals or synthetic compounds or combinations of both, are blended into so-called bodies. These are then shaped into desired forms and fired. The resultant products are hard, dense, and brittle. Further shaping is possible only by grinding. Other compositions can be formed by glass-shaping techniques, such as casting in the molten state or hot pressing.

The demand for complex shapes, close dimensional tolerances, and controlled physical and chemical properties has resulted in new developments in forming techniques. The older methods of slip casting and jiggering are still used for forming electrical porcelain, which contains a considerable amount of plastic clays.

Other methods of forming, particularly adaptable to nonplastic compositions and to line production techniques, are automatic dry pressing, extruding, and injection or compression molding. Filmed casting and stamping of ceramic sheets is another method used for the production of accurately formed thin ceramic shapes, such as capacitor dielectrics or vacuum tube spacers.

Materials

Electrical Porcelain

Porcelain is the outstanding ceramic insulator because it combines mechanical stability and strength with heat and arc resistance and the ability to resist the passage of electric current.

Conventional electrical porcelain is made of the natural minerals clay, flint, and feldspar and is very similar in composition to porcelain used for high-quality vitrified dinnerware. After forming, the ceramic is fired to complete vitrification to develop maximum mechanical and dielectric strength. For outdoor use and at locations exposed to humidity, it is desirable to use insulators with glazed surface. The glaze consists essentially of the same components as the porcelain itself, but in different proportions.

Electrical porcelain is a satisfactory insulator for low-tension electrical wiring systems, for outlets and switches, lamp sockets, and electrical appliances. It is unsurpassed for insulation of outdoor high-voltage power transmission and distribution systems, and is used extensively for suspension and pin-type insulators. Porcelain high-tension insulators also find numerous applications in transformers and as lead-in insulators.

High-Frequency Insulation

A dielectric material for use at high frequencies must have the additional characteristic of low dielectric loss, and its properties must not be affected by changes over the required temperature range.

Porcelain has a rather high dielectric loss under high-frequency conditions, but a number of low-loss ceramic materials have been developed especially for high-frequency insulation. It is generally agreed that a low-loss ceramic body should consist chiefly of uniformly small crystallites bonded with only a very small amount of glassy matrix. Typical special ceramics are frequently named according to the predominant crystalline phase in the ceramic structure, which is the chief contributor to the specific properties of the ceramic product.

Among the best-known high-frequency ceramics are *Steatite* ceramics ($\text{MgO} \cdot \text{SiO}_2$). They are based on the mineral talc or steatite, a hydrous magnesium silicate. Other low-loss ceramic compositions are *Forsterite* ($2\text{MgO} \cdot \text{SiO}_2$), *Wollastonite* ($\text{CaO} \cdot \text{SiO}_2$), *Mullite* ($3\text{Al}_2\text{O}_3 \cdot 2\text{SiO}_2$), and *Spinel* ($\text{MgO} \cdot \text{Al}_2\text{O}_3$).

Sintered Al_2O_3

Highest physical and dielectric strength and low dielectric loss over a wide temperature range is found in a sintered aluminum oxide or Al_2O_3 ceramic. The main crystalline phase is corundum Al_2O_3 .

Sintered Al_2O_3 ceramics are impervious to gases and meet the very exacting requirements of spark plug insulation, of envelopes for ultra-high-frequency receiving and power vacuum tubes. Paper-thin wafers of sintered Al_2O_3 are used as wire supports in vacuum tubes, as a substitute for stamped natural mica spacers.

Thermal Shock-Resistant Electrical Ceramics

Numerous applications in the low- and high-frequency field demand ceramics that will withstand sudden heat shock. For example, insulation for electrical appliances such as toasters, ovens, also electric arc chambers and switch gears, thermocouple insulation, and supports for electrical resistors, are subjected to sudden thermal changes. Low thermal expansion, combined with high heat conductivity, is desirable in ceramics for such applications. The outstanding material in this group is Cordierite ($2\text{MgO} \cdot 2\text{Al}_2\text{O}_3 \cdot 5\text{SiO}_2$). Other ceramics of low thermal expansion are based on the mineral β -Spodumene, a complex lithium aluminosilicate. Both groups of ceramics have lower mechanical strength than steatite and sintered Al_2O_3 , but their excellent thermal shock resistance makes these materials very useful for the applications just mentioned.

Glass

A unique combination of properties has made glass an indispensable material of construction in the electrical industry. Among its most important properties are transmission of light, imperviousness to gases, ability to seal readily to metals, good dielectric properties, and ease of fabrication into many shapes. The chemical composition of glasses vary widely, but in general it can be stated that silica (SiO_2) is the foundation of most commercial glasses, fused with such metallic oxides as soda, potash, Ca, Pb, Ba, Mg, and B.

The properties of glasses are primarily determined by their composition. The most widely used glasses for electrical insulation are of the soda-lime-silicate type, the lead glasses, and the boron aluminosilicate (*Pyrex*) glasses. The major characteristics of the latter type are good mechanical strength, low thermal expansion, good weathering stability, and good dielectric properties.

Glass insulators are used extensively as line insulators for open wire lines, radio antennas, and for envelopes of incandescent lamps, vacuum tubes, and mercury switches, and other devices. In the electronic field, glass serves as an insulation basis for electronic components, such as resistors and inductors and as a dielectric for capacitors.

Certain glasses can be converted into finely crystalline bodies bonded together with a vitreous matrix or by fusion of the crystallites at their grain boundaries (**Pyroceram**). Articles to be converted

from glass to a crystalline ceramic are first fabricated in the glassy state with special nucleating agents added to the glass composition to form crystallites in the body. After forming, crystallization is effected by either exposure to ultraviolet radiation and temperature treatment or by heat treatment alone. The outstanding advantage of this new group of material is that they can be fabricated into a variety of shapes by conventional glass-forming methods and have a higher strength and stability of crystalline ceramics.

Fibrous glass is an important insulating material for electrical equipment. It may be used in the form of yarn, tapes, sleeving, or for reinforcement of organic plastics. On the other hand, plastics improve abrasion resistance and dielectric strength of fibrous glass constructions.

Ceramic Papers

There are a number of ceramic papers on the market that serve as high-temperature electrical insulation in a similar way as fibrous glass. These papers are made from reconstituted mica flakes (*Samica*, *Mica Mat*), clays, or glass and mineral (mullite) fibers.

Glass-Bonded Mica

As the name suggests, this group of materials consists of either natural or synthetic mica flakes that are bonded under heat and pressure by a glassy matrix. Vitrified ceramics can only be lapped or ground with the hardest abrasives, such as SiC, corundum, or diamond powder. In contrast, glass-bonded mica can be subjected to all normal machining operations. The material is impervious to moisture, has high dielectric strength, and can be molded to accurate dimensions. Metal inserts can be molded directly into mica-bonded articles. This is a distinct advantage over other ceramics, which require assembly or attachment of metal parts after processing.

Electronic Ceramics

Great progress has been made during the past decades in the area of solid-state research. Solid-state components are finding many applications in electronics. Some of these, such as diodes, rectifiers, or transistors, are based on single crystals, germanium and silicon, grown from a melt and cut into required shape. These are not considered ceramics, but others based on polycrystalline systems and fabricated by ceramic processes are considered among electric ceramics.

Ferroelectric Ceramics

Ferroelectricity, the spontaneous alignment of electric dipoles under the influence of an electric field, is an outstanding property of certain ceramic materials, especially those based on barium titanate. Besides, barium titanate, additional ferroelectric materials were discovered in the field of niobates, tantalates, and zirconates. Ferroelectric ceramics exhibit a high dielectric constant, which makes them attractive for dielectrics in capacitors. The dielectric constant of these ceramics can be varied through compositional changes; values as high as 10,000 at room temperature can be obtained. Very high dielectric constant ceramics have rather steep negative temperature coefficients of capacity. The capacitance of special barium titanate capacitors is sensitive to applied voltage, which suggests their use as dielectric amplifiers. Nonlinear capacitors of this type have also been employed for frequency modulation and remote tuning devices. Ferroelectric ceramics can be made to show piezoelectric effects, that is, the ability to convert mechanical strain into electric charges and, conversely, the ability to transform a voltage into mechanical force. This is produced by exposing the material to an orienting electric field during the cooling after firing. Piezoelectric ceramics of the barium titanate type have found applications for photograph pickups, ultrasonic thickness gauges,

accelerometers, ultrasonic cutting tools, and even in electromedical instruments for measuring heart conditions.

Ferromagnetic Ceramics

Ferromagnetic ceramics, also known as ferrites, are compounds of various metal oxides and have the general formula $MO \cdot Fe_2O_3$, where M stands for a bivalent metal ion, such as zinc, nickel, magnesium, and others. They are ceramic materials with a crystalline structure of the spinel ($MgO \cdot Al_2O_3$) type. The mineral magnetite ($FeO \cdot Fe_2O_3$) is the only naturally occurring mineral of this type and has been well-known and used for ages as lodestone for its magnetic properties. In contrast to metallic magnetic materials, ceramic ferrites have high-volume resistivity and high permeability. Their specific gravity is between 4 and 5, considerably less than iron (8). They can be made both into "soft" and "hard" permanent magnetic materials. The properties of soft ferrites can be varied over a wide range to meet specific application requirements. For cores of radio and television loop antennas they are made with emphasis on a high-quality (*Q*) factor, to attain optimum in reception quality and selectivity. For memory cores in electron computers, they are so compounded that they exhibit a square hysteresis loop of magnetization and have an extremely low switching time between magnetic saturation and demagnetization. Ceramic magnets are about 35% lower in density than metallic magnets, an important factor for military airborne applications.

Resistor Ceramics

Certain nonmetallics pass limited amounts of electricity and therefore are useful as electrical resistors. Some of these have advantages over metals in that they are more resistant to oxidation and are therefore useful at higher temperatures.

SiC, either self-bonded or bonded with silicon in the form of rods or tubes, is used for resistor heating elements in electric furnaces. These can be heated to 1400°C in air for indefinite periods of time and may be heated as high as 1600°C for shorter periods.

SiC as a resistor element shows nonlinear characteristics and is used where a nonohmic variation of current is desired (Thyrite resistors). Nonlinear resistors of this type are chiefly used for voltage regulation and current suppression, such as in lightning arrestors.

Many oxides become electrically conductive at elevated temperatures. The electrical conductivity of oxides is governed to a large degree by the amount of impurities present. For example, the electrical resistance of thoria is greatly reduced by the presence of such oxides as ceria, yttria, erbia, etc. Thoria and zirconia resistors have been used as electric furnace heating elements up to 2000°C. These oxides are nonlinear with temperature change and therefore have found applications as thermistors. These components are used as temperature sensors and pyrometers, temperature bridges, and microwave power meters.

Other Semiconductor Ceramics

Semiconductor ceramics of silicide, telluride, and oxide compositions have been used for thermoelectric devices, to convert heat directly into electrical energy (Seebeck effect) and for refrigeration (Peltier effect).

Electric Arc Furnace

See *arc furnace*.

Electric Arc Spraying

A thermal spraying process using as a heat source an electric arc between two consumable electrodes of a coating material and a compressed gas, which is used to atomize and propel the material to the substrate.

E

Electric Arc Welding

Any welding operation in which heat is developed by an electric arc. It is implicit that the heat generated is sufficient to melt the components being joined in contrast to arc brazing. The arc may be struck between two consumable electrodes, or between the component and one electrode which can be either consumable or nonconsumable. Where the electrode is consumable it can be a short length of metal rod or a continuous wire or tube. This metal forms part of the weld and is termed filler. The rod or two filler metals may have a coating or tube filling that, if present, contributes to the welding operation in various ways depending on the specific process. It forms a protective gaseous envelope around the arc and molten metal and provides flux to form a slag that removes contaminants from the molten weld metal; it may also contribute metal or alloying elements to the weld metal and modify the arc conditions or weld metal deposition characteristics. Nonconsumable electrodes are of refractory materials particularly tungsten although carbon is occasionally still used in some processes. Metal nonconsumable electrodes are normally inert gas such as argon, helium, or carbon dioxide (effectively inert with steel). The gas is injected into the arc area primarily to form a protective envelope around the arc and molten weld metal but also in some cases to modify arc and metal transfer characteristics. Although the electrode is not consumed, metal may be added to the joint by a separate filler rod. See also *manual metallic arc*, *tungsten inert gas*, *metal inert gas*, and *submerged arc*.

Electric Bonding (Thermal Spraying)

See preferred term *surfacing*.

Electric Brazing

See preferred term *resistance brazing* and *arc brazing*.

Electric Dipole

The result of a distribution of bound charges, that is, separated charges that are bound to their centers of equilibrium by an elastic force; equal numbers of positive and negative charges must be present in an uncharged medium.

Electric Dipole Moment

A quantity characteristic of a distribution of bound charges equal to the vector sum over the charges of the product of the charge and the position vector of the charge.

Electric Dipole Transition

A transition of an atom, molecule, or nucleus from one energy state to another, which results from the interaction of electromagnetic radiation with the dipole moment of the molecule, atom, or nucleus.

Electric Field Effect

See *Stark effect*.

Electric Furnace

A metal melting or holding furnace that produces heat from electricity. They operate on the resistance or induction principle. See also *induction furnace*.

Electric Resistance Welding

See *resistance welding*.

Electric Steel

(1) Steel made by one of the electric melting processes. There is often an implication of good quality, particularly freedom from inclusions. (2) Steel having low magnetic hysteresis, and hence used as sheet for the laminations of transformers and generator stators. Such steels are typically very low carbon with up to 5% silicon and are carefully cold rolled to maximize their magnetic characteristics.

Electric Strength

The maximum voltage that an insulating material can sustain without arcing or break down allowing the passage of a current.

Electrical Conductivity

See *conductivity*, *electrical*.

Electrical Discharge Grinding

Grinding by spark discharges between a negative electrode grinding wheel and a positive workpiece separated by a small gap containing a dielectric fluid such as petroleum oil.

Electrical Discharge Machining (EDM)

Metal removed by a rapid spark discharge between different polarity electrodes, one on the workpiece and the other on the tool separated by a gap distance of 0.013–0.9 mm (0.0005–0.035 in.). The gap is filled with dielectric fluid or paraffin and metal particles which are melted, in part vaporized and expelled from the gap. Complex shapes, deep narrow holes, and high precision can be achieved but surface damage due to the high local temperatures may occur.

Electrical Discharge Wire Cutting

A special form of electrical discharge machining wherein the electrode is a continuous moving conductive wire. Also referred to as traveling wire electrical discharge machining.

Electrical Disintegration

Metal removal by an electrical spark acting in air. It is not subject to precise control, the most common application being the removal of broken tools such as taps and drills.

Electrical Insulators

Any materials that retard the flow of electricity and are used to prevent the passage or escape of electric current from conductors. No materials are absolute nonconductors; those rating lowest on the scale of conductivity are therefore the best insulators. An important requirement of a good insulator is that it does not absorb moisture, which would lower its resistivity. Glass and porcelain are the most common line insulators because of low cost.

Synthetic rubbers and plastics have now replaced natural rubber for wire insulation, but some aluminum conductors are insulated only with an anodized coating of aluminum oxide. Wires to be

coated with an organic insulator may first be treated with hydrogen fluoride, giving a coating of copper fluoride on copper wire and aluminum fluoride on aluminum wire. The thin film of fluoride has high dielectric strength and heat resistance.

Insulating oils are mineral oils of high dielectric strength and high flash point employed in circuit breakers, switches, transformers, and other electrical apparatus. An oil with a flashpoint of 285°F (140°C) and fire point of 310°F (154°C) is considered safe. A clean, well-refined oil will have high dielectric strength, but the presence of as low as 0.01% water will reduce the dielectric strength drastically. The insulating oils, therefore, cannot be stored for long periods because of the danger of absorbing moisture. Impurities such as acids or alkalies also detract from the strength of the oil. Since insulating oils are used for cooling as well for insulating, the viscosity should be low enough for free circulation, and they should not gum. *Askarel* is an ASTM designation for *insulating fluids* which give out only nonflammable gases if decomposed by an electric arc. They are usually chlorinated aromatic hydrocarbons such as trichlorobenzene (TCB), but fluorinated hydrocarbons are also used. Insulating gases are used to replace air in enclosed areas to insulate high-voltage equipment. The insulating oil, fluids, and gases are generally referred to as *dielectrics*, although this term embraces any insulator.

Insulation porcelain, or *electrical porcelain*, is not usually an ordinary porcelain except for common line insulators. For such uses as spark plugs, they may be molded silica, and for electronic insulation they may be molded steatite or specially compounded ceramics, more properly called *ceramic insulators*. Insulation porcelains compounded with varying percentages of zirconia and beryllia have a crystalline structure and good dielectric and mechanical strengths at temperatures as high as 2000°F (1093°C). These porcelains may have some magnesia, but are free of silica. However, zircon porcelain is made from zirconium silicate, and the molded and fired ceramic is equal to high-grade steatite for high-frequency insulation. The material called Nolex by the Naval Surface Weapons Center (NSWC) is made by hot-molding finely powdered synthetic fluorine mica. The molded parts are practically pure mica. They can be machined, have high-dimensional precision because they need no further heat treatment, and have high dielectric strength. Beryllia is a valued insulator for encapsulation coatings on heat-generating electronic devices as it has both high electrical resistivity and high heat conductivity.

Most ceramics are electrical insulators and are used widely for installation of electric power lines. The applications range from structural power insulators to electronic packaging and substrates. The ceramics serve as a structural and insulating base on which electronic components are deposited or attached. The requirement for good surface finish has led to the development of fine-grained alumina material that can be prepared with a very good finish. The requirement for high thermal conductivity in some applications has led to the use of *beryllia*, high-purity *alumina*, and more recently, *aluminum nitride* as substrate materials. Other materials are *silicon carbide* doped with beryllia to give electrical insulation and *glass ceramics* that can easily be produced in the complex shapes often needed. They can also be produced with a tailored thermal expansion coefficient *multilayer ceramic* (MLC) substrate for high-speed computer processing modules.

Electrical Isolation

The condition of being electrically separated from other metallic structures or the environment.

Electrical Pitting

The formation of surface cavities by removal of metal as a result of an electrical discharge across an interface.

Electrical Porcelain

Vitrified *whiteware* having an electrical insulating function.

Electrical Resistance Pyrometer

See *pyrometry*.

Electrical Resistance Strain Gauge

See *strain gauge*.

Electrical Resistance Welding (ERW)

See *resistance welding*.

Electrical Resistivity

The electrical resistance offered by a material to the flow of current, times the cross-sectional area of current flow and per unit length of current path; the reciprocal of the conductivity. It is measured in ohms but also see International Annealed Copper Standard. Also called *resistivity* or *specific resistance*.

Electrical-Contact Materials

These are materials used to make or break electrical contact, thus make-and-break electrical circuits, or to provide sliding or constant contact. Both require high electrical conductivity to ease current flow, high thermal conductivity to dissipate heat, high melting point or range to inhibit arc erosion and prevent sticking, corrosion and oxidation resistance to prevent formation of films that impede current flow, high hardness for wear resistance, and amenability to welding, brazing, or other means of joining. The sliding contact types also require low friction, and a lubricant is always required between the sliding material to prevent seizing and galling.

The materials used range from pure metals and alloys to composites, including those made by powder metallurgy methods. Copper is widely used but requires protection from oxidation and corrosion, such as by immersion in oil, coating, or vacuum sealing. Cu-W alloys or mixtures of Cu-Gr increase resistance to arcing and sticking and some copper alloys provide greater hardness, thus greater wear resistance and better spring characteristics. Silver is more oxidation-resistant in air and, pure or alloyed, is the most widely used metal for make-and-break contacts for application and currents to 600 A. Ag-Cu alloys provide greater hardness but less conductivity and oxidation resistance; Ag-Cd alloys increase resistance to arc erosion and sticking; and Ag-Pt, Ag-Pd, and Ag-Au alloys increase hardness, wear resistance, and oxidation resistance. All alloying elements, however, decrease conductivity. Gold has outstanding oxidation and sulfidation resistance but, being soft and prone to wear and arc erosion, is limited to low-current (0.5 A maximum) applications. To enhance these properties, gold alloys, such as Au-Ag, Au-Cu, Au-Ag-Pt, Au-Ag-Ni, and Au-Cu-Pt-Ag, are more commonly used. Platinum and palladium are also used for contacts, but, again, in alloy form more than as pure metals. Among the most common ones are Pt-Ir, Pt-Ru, Pt-Pd-Ru, Pd-Ru, Pd-Cu, and Pd-Ag. A Pd-Ag-Pt-Au alloy for brushes and sliding contacts is noted for

E

its exceptional modulus of elasticity and high proportional limit. Aluminum, tungsten, and molybdenum are also used for electrical contacts but mainly in composite form. Al used for contacts provides an electrical conductivity of about 60% that of copper, but is prone to oxidation and, thus, is clad or plated with silver, tin, or copper. The refractory metals, although providing excellent resistance to wear and arc erosion, are poor conductors and oxidize readily.

The principal metals made in composite form by P/M methods are the refractory metals, including those in carbide form, and copper-base and silver-base metals. The refractory metals, notably tungsten and molybdenum or their carbides, usually serve as a base for infiltrating with copper or silver, thus combining electrical conductivity and resistance to wear and arc erosion in a single material. Many such composites are common, including W–Cu, W–Ag, WC–Ag, WC–Cu, W–Gr–Ag, and Mo–Ag. The amount of conductive metal may exceed or be less than that of the refractory metal or refractory-metal carbide. A common silver composite is Ag–CdO, which, for a given amount of silver, provides greater conductivity than Ag–Cd alloys as well as greater hardness and resistance to sticking. Others include Ag–Gr, Ag–Ni, and Ag–Fe. The Ag–Gr composites are used mainly for sliding or brush contacts.

Electrical-Resistance Metals and Alloys

This major family of metals, including alloys as well as pure metals, includes alloys used in controls and instruments to measure or regulate electrical performance, heating alloys used to generate heat, and thermostat metals used to convert heat to mechanical energy. There are seven types of electrical-resistance alloys: (1) radio alloys, which contains 78%–98% Cu with the balance Ni; (2) manganins, 87% Cu and 13% Mn or 83%–85% Cu, 10%–13% Mn, and 4% Ni; (3) constantans, 55%–57% Cu and 43%–45% Ni; (4) Ni–Cr–Al alloys, 72%–75% Ni, 20% Cr, 3% Al, and either 5% Mn or 2% Cu, Fe, or Mn; (5) Fe–Cr–Al alloys, 73%–81% Fe, 15%–22% Cr, 4%–5.5% Al; (6) various other alloys, mostly nickel-base alloys, some of which contain substantial amounts of chromium or iron, chromium and iron, chromium and silicon, and, in some cases, magnesium and aluminum, and (7) pure metals, notably aluminum, copper, iron, nickel, precious metals, and refractory metals.

Key characteristics of resistance alloys are uniform resistivity, stable resistance, reproducible temperature coefficients of resistance, and low thermal electric potential vs. copper. Less critical, but also important, are coefficient of thermal expansion (CTE); strength and ductility; corrosion resistance; and joinability to dissimilar metals by welding, brazing, or soldering. Heating alloys require high heat resistance, including resistance to oxidation and creep in particular environments, such as furnaces, in which they are widely used; high electrical resistivity; and reproducible temperature coefficients of resistance. Also desirable are high emissivity, low CTEs, and low modulus to minimize thermal fatigue, strength, and resistance to thermal shock and ductility for fabricability. Thermostat metals, two or more bonded materials of which one may be nonmetallic, are chosen based on different electrical resistivities and thermal expansivities so that applied heat can be converted to mechanical energy.

Electrical resistivity in ohm-circular nohm·m for the alloys encompassed by the seven groups range from 16 for silver to 1450 for an alloy made up of 72.5% Fe, and 5.5% Al. Iron has the highest resistivity, 970, of the pure metals, followed by Ta, 135; Pt, 106; Ni, 80; and W, 55. The radio alloys are in the 50–300 range, the manganins 380–480, the constantans 490–500, and most of the Ni–Cr–Al, Fe–Cr–Al, and various other alloys are in the 1015–1450 range. Temperature coefficients of resistance in parts per million per

degree Celsius range from ± 10 to ± 15 at 15–45°C for the manganins to +6000 at 20–35°C for pure nickel. Tensile strength and ductility also range widely depending on the alloy metal. Maximum operating temperature in air for the commonly used resistance-heating alloys range from 927°C for 43.5% Fe–35% Ni–20% Cr–1.5% Si alloy to 1374°C for 72.5% Fe–22% Cr–5.5% Al. For platinum, this temperature is 1510°C. The refractory metals are suitable for still higher temperatures and vacuum and, in the case of molybdenum and tungsten, in select environments.

Electrical-resistance alloys are mainly wire products, and the alloys have been known by a multitude of trade names. The standard alloy for electrical-resistance wire for heaters and electrical appliances in Ni–Cr, but Ni–Mn and other alloys are used. For high-temperature furnaces, tungsten, molybdenum, and alloys of the more expensive high-melting metals are employed. The much-used alloy with 80% Ni and 20% Cr resists scaling and oxidation to 1177°C, but it is subject to an inner granular corrosion, known as green rot, which may occur in chromium above 816°C unless modified with other elements. The 60%–80% Ni–Cr family of alloys are used in heater elements, resistors, rheostats, resistance thermometers, and in potentiometers.

The Cr–Al–Fe alloys have high resistivity and high oxidation resistance, but have a tendency to become brittle. The Kanthal alloys have 20%–25% chromium with some cobalt and aluminum, and the balance iron. Kanthal A, with 5% aluminum, will withstand temperatures to 1299°C and is resistant to H₂SO₄. The tensile strength is a 13 MPa with elongation of 12%–16%. Kanthal A-1, for furnaces, has an operating temperature to 1373°C.

Cu–Mn alloys have high resistivity and alloys with 96%–98% manganese, although they may be brittle and difficult to make into wire. Addition of nickel makes them ductile, but lowers resistivity. A typical alloy contains 35% Mn, 35% Ni, and 30% Cu.

Other alloys are used for rheostats, electrical heaters for 1093°C temperature operations, and thermocouples up to 1250°C.

Electro Force

The force between electrodes in a spot, seam, and projection weld. See also *dynamic electrode force*, *static electrode force*, and *theoretical electrode force*.

Electro Lead

The electrical conductor between the source of arc welding current and the electrode holder.

Electro-Beam Machining

Removing material by melting and vaporizing the workpiece at the point of impingement of a focused high-velocity beam of electrons. The machining is done at high vacuum to eliminate scattering of the electrons due to interaction with gas molecules. The most important use of electron beam machining is for hole drilling.

Electrochemical Admittance

The inverse of *electrochemical impedance*.

Electrochemical Cell

An electrochemical system consisting of an *anode* and a *cathode* in metallic contact and immersed in our *electrolyte*. The anode and

cathode may be different metals or dissimilar areas on the same metal surface. See also *cathodic protection*.

Electrochemical Corrosion

Corrosion that is accompanied by a flow of electrons between cathodic and an anodic areas on metallic surfaces.

Electrochemical Discharge Machining

Metal removal by a combination of the processes of *electrochemical machining* and *electrical discharge machining*. Most of the metal removal occurs via an anodic dissolution (i.e., ECM action). Oxide films that form as a result of electrolytic action through an electrolytic fluid are removed by intermittent spark discharges (i.e., EDM action). Hence, the combination of the two actions.

Electrochemical (Chemical) Etching

General expression for all developments of microstructure through reduction and oxidation (redox reactions).

Electrochemical Equivalent

(1) The weight of an element or group of elements oxidized or reduced at 100% efficiency by the passage of the unit quantity of electricity. Usually expressed as grams per coulomb. (2) The mass liberated by 1 A of current flowing for 1 s. The electrochemical equivalent of any element is a function of its chemical equivalent which is its atomic weight divided by the valence. Silver, with an electrochemical equivalent of 0.0011183 g, is a reference from which the electrochemical equivalents of other elements are calculated from the formula:

$$\begin{aligned} &\text{Electrochemical equivalent of element Y} \\ &= \frac{0.0011183 \times \text{atomic weight of Y}}{\text{Valence of Y} \times \text{atomic weight of silver}} \end{aligned}$$

Electrochemical Grinding

A process whereby metal is removed by deplating. The workpiece is the anode; the cathode is a conductive aluminum oxide-copper or metal-bonded diamond grinding wheel with abrasive particles. Most of the metal is removed by deplating; 0.05%–10% is removed by abrasive cutting.

Electrochemical Impedance

The frequency-dependent complex-valued proportionality factor ($\Delta E/\Delta i$) between the applied potential or current and the response signal. This factor is the total opposition (Ω or $\Omega \cdot \text{cm}^2$) of an electrochemical system to the passage of charge. The value is related to the *corrosion rate* under certain circumstances.

Electrochemical Machining

(1) Controlled metal removal by anodic dissolution. Direct current passes through flowing film of conductive solution which separates the workpiece from the electrode-tool. The workpiece is the *anode*, and the tool is the *cathode*. (2) Processes utilizing electrochemistry to selectively remove material to shape a component. The process

may utilize the cathode of simple shape which traverses the component being formed in a preplanned pattern to produce the required shape. Alternatively, a cathode with a reverse image of the required form may be progressively moved toward the component. The concentration of current at the points of closest approach then produces the required image on the anode.

Electrochemical Process

The principles of electrochemistry may be adapted for use in the preparation of commercially important quantities of certain substances, both inorganic and organic in nature.

Inorganic Processes

Inorganic chemical processes can be classified as electrolytic, electrothermic, and miscellaneous processes including electric discharge through gases and separation by electrical means. In electrolytic processes, chemical and electrical energy are interchanged. Current passed through an electrolytic cell causes chemical reactions at the electrodes. Voltaic cells convert chemicals into electricity. Electrothermic processes use electricity to attain the necessary temperature for reaction.

Voltaic cells are used for the intermittent production of small amounts of electricity. When the chemicals involved are exhausted and must be replaced, the unit is called a primary cell. A special case of the primary cell is a fuel cell in which the fuel and anoxidizer are fed continuously to the cell, converted to electricity, and the products removed. If exhausted components can be revived by passing electricity backward through the unit, it is called a secondary cell, storage battery, or accumulator. Cells may be connected in parallel or in series to form a battery.

Organic Processes

Organic electrochemistry was once regarded as a tantalizing area with many important laboratory achievements but few successes in commercial practice. The situation has changed, however, in that electroorganic processes are commercially advantageous if they could fulfill either of two conditions: (1) performance under conditions of voltage corresponding thermodynamically to the conversion of an organic group to a reduced or oxidized group, with the cell products relatively easy to isolate and purify; (2) performance of a highly selective, specific technique to make an addition at a double bond, or to split a particular bond (e.g., between carbon atoms 17 and 18 of a complex molecule having 25 carbon atoms).

Selectivity and specificity are highly important in electroorganic processes for the manufacture of complicated molecules of vitamins and hormones—as well as for the medicinal products whose action on pathogenic organisms is a function of their spiral arrangement, steric forms, and resonance.

The electrolytic oxidation and reduction of organic compounds differ from the corresponding and more familiar inorganic reactions only in that organic reactions tend to be complex and have low yields. The electrochemical principles are precisely those of inorganic reactions, while the procedures for handling the chemicals are precisely those of organic chemistry.

Oxidations

Commercial success in inorganic electrochemistry has come about by well-engineered combinations of organic and inorganic techniques in areas where strictly chemical methods are either impossible or inefficient, for example, in catalytic hydrogenation or oxidation.

E

Reductions

Substances that are easy to reduce may be acted on, at the interface of cathodes, with low H_2 overvoltage. Hard-to-reduce materials may require much higher overvoltages, which are reached through either the cathode composition or the current density.

Electrochemical Potential

The partial derivative of the total electrochemical free energy of a constituent with respect to the number of moles of this constituent where all factors are kept constant. It is analogous to the *chemical potential* of a constituent except that it includes the electric as well as chemical contributions to the free energy. The *potential* of an electrode in an electrolyte relative to a *reference electrode* measured under open circuit conditions.

Electrochemical Reaction

A reaction caused by passage of an electric current through a medium that contains mobile ions (as in electrolysis); or, a spontaneous reaction made to cause current to flow in a conductor external to this medium (as in a galvanic cell). In either event, electrical connection is made to the external portion of the circuit via a pair of electrodes. See also *electrolyte*.

Electrochemical Series

Same as *electromotive force series*.

Electrochemical Shaping

This term and electrochemical machining are often used interchangeably but where they are differentiated "Machining" is usually recognized as a general term and "Shaping" refers to the process utilizing a reverse image cathode.

Electrochemistry

The study of the reactions occurring in a liquid electrolyte, that is, an ionic conductor, through which an electric current passes. This current may be externally imposed, it may arise between different metals that are in electrical contact directly as well as through the electrolyte, or it may develop between areas on a component that differ in some respect such as composition, hardness, or environment. This electrically induced activity is termed a voltaic cell, galvanic cell, or electrolytic cell. In such cells, positively charged cations (i.e., ions deficient in an electron) travel through the electrolyte from the anode to the cathode while a balancing flow of negatively charged anions (i.e., ions carrying an extra electron) travel from the cathode to the anode. The formation of metal cations at an anode involves loss of atoms from the metal surface, termed *electrolytic corrosion*, and their arrival at the cathode can involve deposition, that is, *electroplating*. The *electrode potential* or *electrochemical potential* is the voltage developed between the pairs of metals comprising the anode and cathode of the cell and its value depends on the individual metals involved. If a standard electrode is selected, the relative potential of all other metals, in terms of positive/negative and size, can be measured and tabulated. Eventually, the table is usually presented with the corrosion-resistant noble metals at the bottom and the most reactive base metals at the top. Such a table is termed an Electrochemical Series or Galvanic Series although the two are not identical. A metal may have two positions in the series,

and Active state high in the series and a Passive state where it forms an impervious surface corrosion film that resists further attack. The following list indicates the electropotential relative to the saturated calomel electrode, for various metals and seawater. Typically, differences of more than about 0.2 V may give rise to corrosion.

Material	Voltage (V)
Magnesium alloys	-1.6
Zinc alloys	-1.1
Aluminum	-0.9
Aluminum alloys	-0.6 to -0.8
Mild and carbon steels	-0.7
12% Chromium for ferritic steel	-0.45
18% Cr 8% Ni austenitic stainless	-0.2
Lead	-0.55
Tin and solders	-0.45
Copper and high copper alloys	-0.25
Nickel and high nickel alloys	-0.15
Silver	0
Titanium and high titanium alloys	0
Gold	+0.15
Platinum	+0.15

Electrocorrosive Wear

Wear of a solid surface that is accelerated by the presence of a corrosion-inducing electrical potential across the contact interface. This process is usually associated with wear in the presence of a liquid electrolyte in the interface. However, moisture from the air can also facilitate this type of wear when a galvanic wear couple exists and the contacting materials are sufficiently reactive.

Electroplated Nickel Silver (EPNS)

Silver electroplated onto nickel silver for cutlery and similar applications.

Electrode

Compressed graphite or carbon cylinder or rod used to conduct electric current in electric arc furnaces, arc lamps, and so forth.

Electrode (Electrochemistry)

One of a pair of conductors introduced into an electrochemical cell, between which the ions in the intervening medium flow in opposite directions and on whose surfaces reactions occur (when appropriate external connection is made). Indirect current operation, one electrode or "pole" is positively charged, the other negatively. See also *anode*, *cathode*, *electrochemical reaction*, and *electrolyte*.

Electrode (Welding)

(1) In arc welding, a current-carrying rod that supports the arc between the rod and work, or between two rods as in twin carbon-arc welding. It may or may not furnish filler metal. See also *bare electrode*, *covered electrode*, and *lightly coated electrode*. (2) In resistance welding, a part of a resistance welding machine through which current and, in most instances, pressure is applied directly to the work. The electrode may be in the form of a rotating

wheel, rotating roll, bar, cylinder, plate, clamp, chuck, or modification thereof. See also *resistance welding electrode*. (3) In arc and plasma spraying, the current-carrying components which supports the arc. (4) An electrical conductor from which the current leaves the supply circuit to enter the weld zone. In the case of pressure welding, the electrode is usually of a copper base alloy combining high conductivity with hot strength. An electrode for electric arc welding is defined as consumable or nonconsumable depending upon whether it is progressively consumed to provide filler metal to be fused and incorporated in the joint. A covered or coated (consumable) electrode carries an external coating that contributes greatly to the welding process by providing flux, protective gases, filler or alloying elements, or materials that modify the arc characteristics and control the slag characteristics. A cored or flux cored electrode contain similar constituents within the tubular electrode. A sheathed electrode has an external sheath surrounding the coating. There are various electrode classification systems which define the coating, welding characteristics and sometimes the expected properties or other features. Often, such classifications refer to the principal constituent of the coating. A rutile electrode has a coating or core that a substantial proportion of titanium oxide, i.e., rutile. These are general-purpose electrodes, relatively easy to handle in manual applications. A basic electrode has a coating or core that is substantially calcium carbonate and fluoride, that is, chemically basic. Such coatings, suitably handled to keep them dry, release only small quantities of hydrogen compared with rutile, so basic electrodes are sometimes termed Low Hydrogen Electrodes or, where the quantity of hydrogen is specified, Hydrogen Controlled Electrodes. Basic electrodes are used in more demanding applications such as highly restrained joints, alloy steels, etc. They tend to require more operative skill than rutile electrodes. Cellulosic electrodes have coatings or cores with high cellulose contents providing deep penetration and hence are sometimes termed Deep Penetration Electrodes. Iron powder and alloy powder electrodes have coatings or cores contributing iron or alloy elements to the weld metal. Nonconsumable electrodes are necessarily refractory conductors such as tungsten, tungsten alloy, or carbon.

Electrode Cable

Same as *electrode lead*.

Electrode Deposition

The weight of weld metal deposit obtained from a unit length of electrode.

Electrode Extension

The length of unmelted electrode extending beyond the end of the contact tube during welding.

Electrode Holder

A device used for mechanically holding the electrode while conducting current to it.

Electrode Negative

Direct current arc welding with the electrode connected to the negative pole of the supply. See also *reverse polarity* for a caution.

Electrode Polarization

Change of *electrode potential* with respect to a reference value. Often the *free corrosion potential* is used as the reference value. The change may be caused, for example, by the application of an external electrical current or by the addition of an oxidant or reductant.

Electrode Positive

Direct current arc welding with the electrode connected to the positive pole of the supply. See also *reverse polarity* for a caution.

Electrode Potential

The *potential* of an *electrode* in an *electrolysis* as measured against a *reference electrode*. The electrode potential does not include any resistance losses in potential and either the solution or external circuit. It represents the reversible work to move a unit charge from the electrode surface through the solution to the reference electrode.

Electrode Reaction

Interfacial reaction equivalent to a transfer of charge between electronic and ionic conductors. See also anodic reaction and cathodic reaction.

Electrode Setback

In plasma arc welding and cutting, the distance the electrode is recessed behind the constricting orifice measured from the outer face of the nozzle.

Electrode Skid

In spot, seam, or projection welding, the sliding of an electrode along the surface of the work.

Electrodeposition

(1) The deposition of a conductive material from a plating solution by the application of electrical current. (2) The deposition of a substance on an electrode by passing electric current through an electrolyte. *Electrochemical (plating)*, *electroforming*, *electrorefining*, and *electrowinning* result from electrodeposition.

Electroformed Molds

A mold for forming plastics made by electroplating metal on the reverse pattern of the cavity. Molten steel may then be sprayed on the back of the mold to increase its strength.

Electroformed Parts

Electroforming is essentially an electrolytic plating process for manufacturing metal parts. In general, it is best to consider electroforming for applications where a part is impossible or difficult to make by any other standard method or if the tooling required by another method such as forging or die-casting is extremely expensive. Electroforming is not generally used for large-quantity production because it is a batch operation. It is, however, valuable for short-run, simple parts or long-run, complicated parts because of its low tooling costs.

E

Electroforming is the technology of creating exact (mirror image) copies of uniquely shaped objects by electrodepositing a layer of heavy metal onto an original and subsequently separating the two.

Self-supporting parts can be made from such metals as Ni, Cu, Fe, Ag, Cr, and Au. In all instances, the pure metal has been found to be the only practical deposit obtainable. There are, however, a number of bimetallic deposits such as cobalt and/or nickel and tungsten.

Nickel is neither the toughest nor the most corrosion-resistant metal, and yet it is becoming more popular with plastic molders. Uniquely suited for one application in particular—mold insert electroforming—nickel makes possible the cost-effective mass production of many of today's advanced products. Today, the process is used to manufacture so-called Fresnel lenses, used in overhead projectors, as well as many other plastic optical products. A single precision-machined mandrel generates numerous inserts, assuring that each molded optical component exhibits the same geometric characteristics and surface finish essential for consistent optical performance. Nickel molds electroformed have high dimensional stability (meaning they display minimal warping), have an optical-quality surface finish, and exhibit the durability necessary to produce thousands of precision lenses using only a few electroformed mold inserts.

Among the easiest metals to electroplate out of environmentally benign aqueous solutions, nickel is the logical choice for electroformed tooling. Nickel is also sufficiently strong, hard, and tarnish-resistant to withstand molding conditions encountered in the processing of many popular plastics. Moreover, it is also easily machinable, brazeable, and weldable.

Advantages

Following are the chief advantages of electroforming:

1. Initial tooling costs are extremely low. This has several advantages. Short-run parts can be produced to determine market acceptability and, as is the case in missile and aircraft applications, small numbers of parts may be produced economically. The low initial tooling cost makes it economically possible to try various shapes and configurations without undue tooling charges.
2. Because this is an electrochemical process, the surface finish of the mandrel is duplicated exactly, thereby providing a means of producing parts to any surface finish—from a high polish to a surface resembling gravel. Many examples of these are found in industry. Among them are molds to make records, plastic tile resembling different fabric textures, and surface finish standards.
3. Complex shapes such as ducting and tubing may be made in one piece, thereby eliminating welding and soldering.
4. Parts requiring extremely close tolerances are easily made by the electroforming process, inasmuch as the mandrel or shape upon which the metal is deposited may be machined or produced to extremely close tolerances, inspected easily, and thereby duplicated exactly. Examples of extremely close tolerance parts that can be made are radar plumbing, hot-air ducting and tubing, wind-tunnel test nozzles and liners, reflectors, collectors, mirrors, nose cones, etc.

Sizes

Parts produced by electroforming range in size from miniature to extremely large. Typical miniature parts such as small electronic devices are 0.50–0.76 mm in diameter and 3.2 mm long with a wall thickness of 0.03 ± 0.01 mm. Large sizes may be as big as 4.8 m in diameter. Thicknesses also may vary from 0.03 to 25.4 mm or even thicker.

Parts such as wind-tunnel nozzles 4.8 m long, 762 mm in diameter, and varying in thickness, have been fabricated from 1.5 to 25.4 mm. Tolerances on a part like this are extremely close and are usually ± 0.03 mm in the throat area and ± 0.05 mm in the downstream sections. Tolerances on waveguide plumbing may be as close as ± 0.01 mm.

The range of mechanical properties of the materials that may be deposited by electroforming are shown next:

Material	Brinell Hardness, Bhn	Ultimate Tensile Strength, MPa	Yield Strength, MPa	Elongation, % in 2 in.
Nickel	140–500	379–1552	276–862	2–20
Copper	51–170	248–552	83–276	21–39

Electroforming

The deposition, by electroplating, of metal onto a shaped former or die. The die is coated with some conducting release agent so that when a suitable thickness of metal has been deposited it can be lifted off providing an image of the die. Highly complex and detailed shapes can be produced.

Electroalvanizing

Zinc coating of iron or steel by electroplating. See also *cathodic protection*.

Electroslag Welding (EGW)

(1) A *vertical position* arc welding process which produces coalescence of metals by heating them with an arc between a continuous filler metal (consumable) electrode and the work. Copper dams (molding shoes) are used to confine the molten weld metal. The electrodes may be either flux cored or solid wire. Shielding may or may not be obtained from an externally supplied gas or mixture. See also *gas metal arc welding* and *flux cored arc welding*. (2) Similar to electroslag welding except that the arc and weld pool are shielded by a gas rather than a slag and the arc is maintained throughout the process.

Electrohydraulic Forming

Processes in which thin components submerged in a liquid are formed by the shock wave produced by electrical discharge between a pair of submerged electrodes.

Electrokinetic Potential

This *potential*, sometimes called zeta potential, is a potential difference in the solution caused by residual, unbalanced charge distribution in the adjoining solution, producing a double layer. The electrokinetic potential is different from the *electrode potential* in that it occurs exclusively in the solution phase; that is, it represents the reversible work necessary to bring a unit charge from infinity in the solution up to the interface in question but not through the interface.

Electroless Plating

This is a chemical reduction process that, once initiated, is autocatalytic. The process is similar to electroplating except that no outside

current is needed. The metal ions are reduced by chemical agents in the plating solutions, and deposited on the substrate. Electroless plating is used for coating nonmetallic parts. Decorative electroless plates are usually further coated with electrodeposited nickel and chromium. There are also applications for electroless deposits on metallic substrates, especially when irregularly shaped objects require uniform coating. Electroless copper is used extensively for printed circuits, which are produced either by coating the nonmetallic substrate with a very thin layer of electroless copper and electroplating to the desired thickness or by using the electroless process only. Electroless iron and cobalt have limited uses. Electroless gold is used for microcircuits and connections to solid-state components. Deeply recessed areas that are difficult to plate can be coated by the electroless process.

Nonmetallic surfaces and some metallic surfaces must be activated before electroless deposition can be initiated. Activation on nonmetals consists of the application of stannous and palladium chloride solutions. Once electroless plating is begun, it will continue to a desired thickness; that is, it is autocatalytic. The process does differ from a displacement reaction, in which a more noble metal is deposited while a less noble one goes into solution; this ceases when the more noble deposit, if pore-free, covers a less noble substrate.

Electroluminescence

The direct conversion of electrical energy into light.

Electrolysis

(1) Chemical change resulting from the passage of electric current through an *electrolyte*. (2) The separation of chemical components by the passage of current through an electrolyte.

Electrolyte

This is a material that conducts an electric current when it is fused or dissolved in a solvent, usually H_2O . Electrolytes are composed of positively charged species, called cations, and negatively charged species, called anions. For example, $NaCl$ is an electrolyte composed of sodium cations (Na^+) and chlorine anions (Cl^-). The ratio of cations to anions is always such that the substance is electrically neutral. If two wires connected to a lightbulb and to a power source are placed in a beaker of H_2O , the lightbulb will not glow. If an electrolyte, such as $NaCl$, is dissolved in the H_2O , the lightbulb will glow because the solution can now conduct electricity. The amount of electric current that can be carried by an electrolyte solution is proportional to the number of ions dissolved. Thus, the bulb will glow more brightly if the amount of $NaCl$ in the solution is increased.

Hydration

H_2O is a special solvent because its structure has two different sides. On one side is the O_2 atom, and on the other are two H_2 atoms. Covalent molecules, such as H_2O , are held together by covalent bonds, which are formed when two atoms share a single pair of electrons. However, when two different atoms form a covalent bond, the sharing of electrons is not always equal. An electron in a covalent bond between two different atoms might spend more time near one atom or the other. In H_2O , the electrons from the $O-H$ bonds spend more time near the O_2 atom than near the H_2 atoms. As a result, the O_2 has somewhat more negative charge than the H_2 atoms. This phenomenon is not the same as ionization, where the electron is completely transferred from one atom to the other, so to indicate the

difference; the O_2 is said to have a partial negative charge (δ^-) and the H_2 to have a partial positive charge (δ^+).

When H_2O molecules surround dissolved ions, the ions are said to be hydrated. The electrostatic attraction associated with hydration provides the energetic driving force for dissolving ions.

Electrolytic Brightening

Same as *electropolishing*.

Electrolytic Cell

An assembly, consisting of a vessel, electrodes, and an electrolyte, in which *electrolysis* can be carried out. See *electrochemistry*.

Electrolytic Cleaning

A process of removing soil, scale, or corrosion products from a metal surface by subjecting it as an *electrode* to electric current in an electrolytic bath. See *electrochemistry*.

Electrolytic Copper

(1) Copper that has been refined by the electrolytic deposition, including cathodes that are the direct product of the refining operation, refinery shapes cast from melted cathodes, and, by extension, fabricators' products made therefrom. Usually, when this term is used alone, it refers to a electrolytic tough pitch copper without elements other than oxygen being present in significant amounts. See also *tough pitch copper*. (2) One of a number of grades of high purity copper, typically 99.95% or better, and hence having a high conductivity. They have in common an origin as *cathode copper*.

Electrolytic Corrosion

Corrosion by means of electrochemical or mechanical action. See *electrochemistry*.

Electrolytic Deposition

Same as *electrodeposition*.

Electrolytic Dissociation

The process in which a substance splits into positively and negatively charged ions. See *electrochemistry*.

Electrolytic Etching

See *anodic etching*.

Electrolytic Extraction

Removal of phases by using an electrolytic cell containing an electrolyte that preferentially dissolves the metal matrix. See also *extraction*.

Electrolytic Grinding

A combination of grinding and machining wherein a metal-bonded abrasive wheel, usually diamond, is the *cathode* in physical contact

E

with the anodic workpiece, the contact being made beneath the surface of a suitable electrolyte. The abrasive particles produce grinding action as nonconducting spacers permitting simultaneous machining through electrolysis.

Electrolytic Lead

A high-purity grade of lead, 99.995% or better, produced by electrolytic refining.

Electrolytic Machining

The removal of material in a selective, controlled manner to achieve a predetermined shape and dimensions desired. See *electrochemistry* and *electrochemical machining*.

Electrolytic Pickling

Pickling in which electric current is used, the work being one of the electrodes.

Electrolytic Polishing

An electrochemical polishing process in which the metal to be polished is made the *anode* in an electrolytic cell where preferential dissolution at high points in the surface topography produces a specularly reflective surface. Also referred to as *electro-polishing*.

Electrolytic Powder

Powder produced by electrolytic deposition or by pulverizing of an electrodeposit.

Electrolytic Protection

See preferred term *cathodic protection*.

Electrolytic Tough Pitch

A term describing the method of raw copper preparation to ensure a good physical- and electrical-grade copper-finished product.

Electromagnetic Focusing Device

See *focusing device*.

Electromagnetic Forming

A process for forming metal by the direct application of an intense, transient magnetic field. The workpiece is formed without mechanical contact by the passage of a pulse of electric current through a forming coil. Also known as magnetic pulse forming.

Electromagnetic Interference

Interference related to accumulated electrostatic charge in a nonconductor.

Electromagnetic Lens

An electromagnet designed to produce a suitably shaped magnetic field for the focusing and deflection of electrons or other charged particles in electron-optical instrumentation.

Electromagnetic Radiation

Energy propagated at the speed of light by an electromagnetic field. The electromagnetic spectrum includes the following approximate wavelength regions: they range from gamma-rays with a wavelength ($\text{\AA}$) of 0.005 to 1.40 (0.005–0.14 nm) to microwaves (3×10^6 – 1×10^{10} (0.3 mm–1 m).

Electromagnetism

Magnetism caused by the flow of electric current.

Electromechanical Polishing

An attack-polishing method in which the chemical action of the polishing fluid is enhanced or controlled by the application of an electric current between the specimen and the polishing wheel.

Electrometallizing/Metallization

The deposition, by electrochemical techniques, of a metallic coating onto a nonmetallic and, usually, nonconducting substrate.

Electrometallurgy

An imprecise term referring to metallurgical processes that use electricity as a primary power source. In some contexts, the term is limited to processes based on electrochemistry, for example, electroplating or electrolytic refining. Other contexts include processes where electricity is the critical power source, for example, melting in an electric arc furnace. However, secondary uses of electricity, for example, for lighting, motor power or instrumentation or even electric arc welding would not be included.

Electrometric Titration

A family of techniques in which the location of the endpoint of a *titration* involves the measurement of, or observation of changes in, some electrical quantity. Examples of such quantities include potential, current, conductance, frequency, and phase.

Electromotive Force

(1) The force that determines the flow of electricity; a difference of electric potential. (2) Electrical potential; voltage.

Electromotive Force Series (emf Series)

A series of elements arranged according to their *standard electrode potentials*, with “noble” metals such as gold being positive and “active” metals such as zinc being negative. In corrosion studies, the analogous the more practical *galvanic series* of metals is generally used. The relative positions of a given metal are not necessarily the same in the two series.

Electron

An elementary particle that is the negatively charged constituent of ordinary matter. The electron is the lightest known particle processing an electric charge. Its rest mass is $m_e \equiv 9.1 \times 10^{-28}$ g, approximately 1/1836 of the mass of the proton or neutron, which are, respectively, the positively charged and neutral constituents

of ordinary matter. The negatively charged subatomic particle that (simplistically) circles the nucleus of an atom. It has a charge of -1.6×10^{-19} coulomb. See *atom* and *inter atomic bonding*.

Electron Bands

Energy states for the free electrons in a metal, as described by the use of the band theory (zone theory) of electron structure. Also called Brillouin zones.

Electron Beam

A stream of electrons in electron-optical systems.

Electron Beam Analysis

Same as *electron probe analysis*.

Electron Beam Cutting

A cutting process that uses the heat obtained from a concentrated beam composed primarily of high-velocity electrons, which impinge upon the workpieces to be cut; it may or may not use an externally supplied gas.

Electron Beam Gun

A device for producing and accelerating electrons. Typical components include the emitter (also called the filament or cathode) that is heated to produce electrons and via thermionic emission, a cup (also called the grid or grid cup), and the anode.

Electron Beam Gun Column

The electron beam gun plus auxiliary mechanical and electrical components which may include beam alignment, focus, and deflection coils.

Electron Beam Welding

A welding process that produces coalescence of metals with the heat obtained from a concentrated beam composed primarily of high-velocity electrons impinging upon the surfaces to be joined. Welding can be carried out at atmospheric pressure (nonvacuum), medium vacuum (approximately 10^{-3} to 25 torr), or high vacuum (approximately 10^{-6} to 10^{-3} torr).

Electron Cloud

The valence electrons of a metallic crystal are not tied to individual atoms that are shared as a general cloud. See *interatomic bonding*, *band theory*, and *semiconductor*.

Electron Compound

An intermediate phase on a phase diagram, usually a binary phase, that has the same crystal structure in the same ratio of valence electrons to atoms as those of intermediate phases in several other systems. An electron compound is often a solid solution of variable composition and good metallic properties. Occasionally, an ordered arrangement of atoms is characteristic of the compound, in which

case the range of composition is usually small. Phase stability depends essentially on electron concentration and crystal structure and has been observed at valence-electron-to-atom ratios of 3/2, 21/13, and 7/4. Beta compounds with a ratio of 3/2 (i.e., three electrons to two atoms), Epsilon with 7/4, and Gamma with 21/13 are the most common examples.

Electron Density

The number of electrons in unit volume of material. Depending upon the context, the electrons counted may be either the total in the substance or merely the conduction electrons.

Electron Emission

The ejection of electrons from a free surface.

Electron Energy Loss Spectroscopy (EELS)

A spectrographic technique in the electron microscope that analyzes the energy distribution of the electrons transmitted through the specimen. The energy loss spectrum is characteristic of the chemical composition of the region being sampled.

Electron Flow

A movement of electrons in an external circuit connecting an *anode* and *cathode* in a corrosion cell; the current flow is arbitrarily considered to be in an opposite direction to the electron flow.

Electron Gun

A device for producing and accelerating a beam of electrons.

Electron Image

A representation of an object formed by a beam of electrons focused by an electron-optical system. See also *image*.

Electron Lens

A device for focusing an electron beam to produce an image of an object.

Electron Micrograph

A reproduction of an image formed by the action of an electron beam on a photographic emulsion.

Electron Microscope

An electron-optical device that produces a magnified image of an object. Detail may be revealed by selective transmission, reflection, or emission of electrons by the object. Instruments using an electron beam, in a vacuum, to examine specimens. The image is displayed on a screen similar to a television set but is also readily photographed. In a transmission electron microscope (TEM), the fixed beam travels through the very thin specimen. In a scanning electron microscope (SEM), the beam scans rapidly back and forth across, as reflected from, the specimen surface. Both instruments offer very high magnifications with resolution of up to about $1 \text{ \AA}$

E

compared with the $0.2\ \mu$ of the light microscope. The SEM has the major advantage that, unlike the conventional light microscope, it can examine surfaces that are rough or inclined to the beam, for example, fracture faces. Hence, much metallurgical SEM work is performed that magnification is below 1000 $\times$, that is, within the range of the light microscope. See also *Electron Probe Analysis*. See also *scanning electron microscope* and *transmission electron microscope*.

Electron Microscopy

The study of materials by means of an electron microscope.

Electron Microscopy Impression

See *impression*.

Electron Multiplier Phototube

See *photomultiplier tube*.

Electron Octet

The eight electrons forming the filled outer valence shell of an atom. This configuration is very stable; the elements having it are inert and the molecules having it are stable.

Electron Optical Axis

The path of an electron through an electron-optical system, along which it suffers no deflection due to lens fields. This axis does not necessarily coincide with the mechanical axis of the system.

Electron Optical System

A combination of parts capable of producing and controlling a beam of electrons to yield an image of an object.

Electron Pair

Two electrons having parallel but opposite spin axes to give a net magnetic moment of zero.

Electron Probe (Analysis)

(1) A facility on an electron microscope for analysis of small surface areas. (2) A narrow beam of electrons used to scan or illuminate an object or screen.

Electron Probe X-Ray Microanalysis (EPMA)

A technique in analytical chemistry in which a finely focused beam of electrons is used to excite an x-ray spectrum characteristic of the elements in a small region of the sample. Conventional mapping determines elemental location and concentration.

Electron Scattering

Any change in the direction of propagation or kinetic energy of an electron as a result of a collision.

Electron Spin

The angular rotational motion of an electron which results in the magnetic moment.

Electron Spin Residence (ESR) Spectroscopy

A form of spectroscopy similar to nuclear magnetic resonance, except that the species studied is an unpaired electron, not a magnetic nucleus.

Electron Trajectory

The path of an electron.

Electron Velocity

The rate of motion of an electron.

Electron Wavelength

The wavelength necessary to account for the deviation of electron rays in crystals by wave-diffraction theory. It is numerically equal to the quotient of *Planck's constant* divided by the electron momentum.

Electronegativity

The ability of the atom of an element to retain or gain electrons in interatomic bonds with other elements.

Electronic Beam Heat Treating

A selective surface hardening process that rapidly heats a surface by direct bombardment with an accelerated stream of electrons.

Electronic Beam Microprobe Analyzer

An instrument for selective analysis of a microscopic component or feature in which an electron beam bombards the point of interest in a vacuum at a given energy level. Scanning of a larger area permits determination of the distribution of selected elements. The analysis is made by measuring the wavelengths and intensities of secondary electromagnetic radiation resulting from the bombardment.

Electronic Ceramics

See *ceramics*.

Electronic Diffraction

The phenomenon or the technique of producing diffraction patterns through the incidence of electrons upon matter. See also *diffraction pattern*.

Electronic Heat Control

A device for adjusting the heating value (rms value) of the current in making a resistance weld by controlling the ignition or firing of the electronic devices in an electronic contactor. The current is initiated each half-cycle at an adjustable time with respect to the zero point of the voltage wave.

Electronic Microscope Column

The assembly of gun, lenses, specimen, and viewing and plate chambers. See also *scanning electron microscope*.

Electronic Packaging

The technical discipline of designing a protective enclosure for an electronic circuit so that it will both survive and perform under a plurality of environmental conditions.

Electronic Phenomena (Mechanisms)

These involve the activities of electrons on a subtle and individual scale and usually low current and are termed electronic; examples include thermionic valves, transistors and equipment where such components are the primary features such as television sets, computers, and modern cash machines. Phenomena and mechanisms that involve electron flow in bulk, often at high current, are better termed electrical; examples include motors and heaters although these may have control systems that are electronic.

Electrophoresis

The movement of colloidal particles, or other finely divided particulate matter suspended in a fluid, which is electrically charged by, and then responds to, an external electrical field.

Electrophoretic Plating

The deposition on an immersed surface of finely divided particulate or colloidal material by application of an electrical field.

Electroplate

The application of a metallic coating on a surface by means of an electrolytic action.

Electroplating

The electrodeposition of an adherent metallic coating on an object serving as a *cathode* for the purpose of securing a surface with properties or dimensions different from those of the basis metal.

Electroplated Coatings

Electroplating may be defined as the electrodeposition of an adherent metallic coating upon an electrode for the purpose of securing a surface with properties or dimensions different from those of the base metal. It must not be confused with electroforming or "electroless plating." "Brush plating," on the other hand, is a special method of electroplating.

In brush plating, the anode may be soluble or insoluble. It is covered with a cloth or similar spongelike material and moistened with the plating solution while it is gently moved back and forth across the surface to be plated. It is usually used for specialized applications.

Electroplating is extensively used to produce printed circuit boards. Its main advantage is that the circuit can be produced directly rather than having to be etched out of a piece of copper sheet. Electroplating is also widely used to impart corrosion resistance. Most parts of automobile bodies are zinc plated for corrosion resistance. Because zinc is more readily attacked by most corrosive

agents that automobiles encounter than steel, it provides galvanic or sacrificial protection. An electrolytic cell is formed in which zinc, the less noble metal, is the anode and the steel, the more noble one, is the cathode. The anode corrodes and the cathode is protected. Zinc also provides a good base for paint. If a metal is more noble than the one on which it is electroplated, it provides protection against corrosion only if it is completely continuous. If a small area of the substrate is exposed such as under a pinhole, corrosion occurs there, rapidly forming a pit.

An example of an electroplated coating applied primarily for wear resistance is hard chromium on a rotating shaft. Electroplating is also used to build up worn or undersized parts. Gold-plated jewelry is an example of a decorative application. Gold and also palladium are electrodeposited on electrical contacts. Here, the absence of an oxide film avoids the rise in the electrical resistance of the contact. Nickel and aluminum are plated for some decorative applications; however, their wide use in the automotive industry has diminished considerably, primarily because of the associated environmental problems. Magnetic components made of such alloys as **Permalloy** can be manufactured by electroplating.

Process

The electroplating process consists essentially of connecting the parts to be plated to the negative terminal of a DC source and another piece of metal to the positive pole, and immersing both in a solution containing ions of the metal to be deposited. The part connected to the negative terminal becomes the cathode, and the other piece is the anode. In general, the anode is a piece of the same metal that is to be plated. Metal dissolves at the anode and is plated at the cathode. If the current is used only to dissolve and deposit the metal to be plated, the process is 100% efficient. Often, fractions of the applied current are diverted to other reactions such as the evolution of H_2 at the cathode; this usage results in lower efficiencies as well as changes in the acidity (pH) of the plating solution. In some processes, such as chromium plating, a piece of metal that is essentially insoluble in the plating solution is the anode. When such insoluble anodes are used, metal ions in the form of soluble compounds must also be added periodically to the plating solution. The anode area is generally about the same as that of the cathode; in some applications it is larger.

Most plating solutions are of the aqueous type. There is a limited use of fused salts or organic liquids as solvents. Nonaqueous solutions are employed for the deposition of metals such as aluminum that have overvoltages lower than H_2 . Such metals cannot be plated in the presence of H_2O , as H_2 would be preferentially reduced.

In addition to metal ions, plating solutions contain relatively large quantities of various substances used to increase the electrical conductivity, to buffer, and in some instances to form complexes with the metal ions. Relatively small amounts of other substances, which are called addition agents, are also present in plating solutions to level and brighten the deposit, to reduce internal stress, to improve the mechanical properties, and to reduce the size of the metal crystals or grains or to change their orientation.

The quantity of metal deposited, that is, the thickness, depends on the current density (A/m), the plating time, and the cathode efficiency. The current is determined by the applied voltage, the electrical conductivity of the plating solution, the distance between anode and cathode, and polarization. Polarization potentials develop because of the various reactions and processes that occur at the anode and cathode, and depend on the rates of these reactions, that is, the current density. If the distance between anode and cathode varies because the part to be plated is irregular in shape, the thickness of the deposit may vary. A quantity

E

called the throwing power represents the degree to which a uniform deposit thickness is attained on areas of the cathode at varying distances from the anode. Good throwing power results if the plating efficiency is low because of polarization where the current density is high.

Plating of Specific Metals

Most metals can be electroplated from either aqueous or fused-salt solutions. The more important metals plated from aqueous baths are Cr, Cu, Au, Ni, Ag, Sn, and Zn. Alloys can also be electroplated. Electrodeposited Cu–Zn and Pb–Sn alloys are used extensively.

Chromium

Electroplated chromium is used primarily to produce wear and corrosion-resistant coatings. Chromium is not deposited for decorating purposes as extensively as in the past because of the associated pollution problem from the discharge of hexavalent chromium. Chromium plating solutions consist primarily of Cr_2O_3 , H_2SO_4 , and H_2O .

Copper

Electroplated copper is used extensively in the manufacture of printed circuit boards. Because copper cannot be directly plated on the insulating material substrates, they must be rendered electrically conductive first. The main advantage of using electrolytically deposited copper to produce printed circuits is that the areas of the board that are made conductive can be controlled. The actual circuit can be produced by selective etching or selective plating involving techniques such as photosensitizing, photoresist, and etch resist. Areas exposed through a mask can become conductive by coating them with electroless copper after activation with a solution of stannous and palladium chloride. Suitable organic materials are also used to render the board conductive. The areas made conductive serve as a substrate for copper electrodeposition. Some circuits are produced only with electroless plating of copper. Only the through holes are plated, generally with electroplated copper over electroless plated copper when the boards are made by laminating copper sheet to the plastic substrate. The copper segments of the printed circuit may be coated with an electroplated Sn–Pb alloy to facilitate subsequent soldering and also to protect them from oxidation. Gold deposits are also used for this purpose. There are other uses of electroplated copper in the electronic industry, such as in the production of microchips. Electroplated copper is also the undercoat for decorative Ni–Cr deposits.

Gold

Gold plating is used for electrical contacts that must remain free of oxides, connections for microcircuits, certain information-storage devices, solid-state components, and jewelry. The use of gold for electrical and electronic application exceeds that for decorative purposes. Electroplated palladium is being substituted for gold in some applications.

Nickel

Nickel coatings covered with chromium provide corrosion-resistant and decorative finishes for steel, brass, and zinc-base die castings. The most widely used plating solution is the Watts bath, which contains nickel sulfate, nickel chloride, and boric acid. All-chloride, sulfamate, and fluoroborate plating solutions are also used. The sulfamate solution is used for low-stress applications. There are a number of compounds, mostly organic, which can be added to nickel-plating baths.

Silver

The principal use of silver electrodeposits is for tableware because of their corrosion resistance (except to sulfur-containing foods) and pleasing appearance. Other important uses are for bearings and electrical circuits, waveguides, and hot-gas seals. The plating solutions are of the cyanide type and generally contain additives that produce bright deposits.

Tin

Tin is used in electrodeposition as a component of solders. Solder is electroplated over copper to protect it from oxidation and to facilitate subsequent joining operations. The advantage of electroplating the solder is that it can be applied only where it is needed. Because of the desirability of eliminating lead in solders, those with higher tin contents are used.

Tin-plated steel for cans in which food is preserved has limited use, because lacquers are preferred to prevent contact between steel and food. Tin plating is employed for refrigerator coils and bearing surfaces. Bright pore-free surfaces can be produced by melting the electroplated tin and allowing it to “reflow.”

Stannous chloride and stannous sulfate are the main components of acid tin-plating solutions.

Zinc

The sacrificial protection of steel against corrosion is the main reason for plating zinc. It is used extensively in the automobile industry for this purpose. Screws, bolts, and washers are barrel-plated with zinc also for corrosion protection. Continuous zinc electroplating of wire and strip is another application. The advantage of electro-depositing zinc over hot dipping is the ability to apply thinner coatings and higher purity.

Properties of Electrodeposits

In the various applications of electrodeposits, certain properties must be controlled and, therefore, must be measured. The properties of electroplated metal that should be considered, depending on the use of the deposit, are thickness, adhesion to substrate, brightness, corrosion resistance, wear resistance, the mechanical properties of yield strength, tensile strength, ductility, and hardness, internal stress, solderability, density, electrical conductivity, and the magnetic characteristics.

Electropolishing

A technique commonly used to prepare metallographic specimens, in which a high polish is produced in making the specimen the *anode* in an *electrolytic cell*, where preferential dissolution at high points smooths the surface. Also referred to as *electrolytic polishing*.

Electrorefining

Using electric or electrolytic methods to convert impure metal to purer metal, or to produce an alloy from impure or partly purified raw materials.

Electrorheological (ER) Fluids

Suspensions of fine particles, usually polymers, in nonconducting oils or other liquids. When electric current is passed through them, they turn from liquid to Jell-O-like solids or vice versa in 0.001–0.0001 s. With the amount of applied voltage governing the degree of solidity, the fluid itself can perform various control functions,

such as damping shock and vibration. Particles include *aluminosilicate zeolites* and *polyacene quinones*. The most common fluids are *silicone oils*, *gasoline*, and *kerosene*.

Electroslag Remelting (ESR)

A *consumable-electrode remelting* process in which heat is generated by the passage of electric current through a conductive slag. The droplets of metal are refined by contact with the slag.

Electroslag Welding

A process in which the two faces to be welded, usually the edges of thick plates, are set vertically and spaced with a wide gap between them. The bottom of the gap is closed by a starter plate and the two sides are closed by movable water-cooled copper shoes. A granulated flux is placed in the enclosure and an arc struck between a filler wire or wires and the starter plate. The arc melts the flux, which then conducts the current, remains molten and melts the continuously fed filler. The arc is extinguished after the flux commences to carry the current. The molten filler beneath the flux layer fuses with the parent plates, the copper shoes commence moving upwards and a weld is formed between the two plates. The resistance heated slag not only melts filler-metal electrodes as they are fed into the slag layer, but also provides shielding for the massive weld puddle characteristic of the process.

Electroslag Welding Electrode

A filler metal component of the welding circuit through which current is conducted between the electrode guiding member and the molten slag (flux).

Electrostatic Lens

A lens producing a potential field capable of deflecting electron rays to form an image of an object.

Electrostatic Precipitator

Equipment in which a gas is passed across a high-voltage field to extract dust. The particles collect an electrical charge and are attracted to catcher troughs that direct them into hoppers.

Electrostrictive Effect

The reversible interaction, exhibited by some crystalline materials, between an elastic strain and an electric field. The direction of the strain is independent of the polarity of the field. Compare with *piezoelectric effect*.

Electrotinning

Electroplating tin on an object.

Electrotwinning

Recovery of a metal from an ore by means of electrochemical processes.

Electrotyping

The production of printing plates by *electroforming*.

Electrovalent Bonding

See *interatomic bonding*.

Element

A substance that can exist as a single atom. See *atomic structure*. There are 92 naturally occurring elements such as hydrogen, iron, chlorine, uranium, etc., plus a dozen or so man-made.

Elevation

In the context of engineering drawings, it is a joining of the appearance as viewed from the end (end elevation), or the side (side elevation), as opposed to alternative views such as plan (viewed from above) or section.

Elliptical Bearing

See *lemon bearing (elliptical bearing)*.

Elongated Alpha

A fibrous structure in titanium alloys brought about by unidirectional metalworking. It may be enhanced by the prior presence of blocky and/or grain boundary α .

Elongated Grain

A grain with one principal axis slightly longer than either of the other two.

Elongation

(1) A term used in mechanical testing to describe the amount of extension of a test piece when stressed. (2) In tensile testing, the increase in the gauge length, measured after fracture of the specimen within the gauge length, usually expressed as a percentage of the original gauge length. See also *elongation, percent*.

Elongation at Break

Elongation recorded at the moment of rupture of a specimen, often expressed as a percentage of the original length.

Elongation, Percent

The extension of a uniform section of a specimen expressed as a percentage of the original gauge length:

$$\text{Elongation, \%} = \frac{(L_x - L_o)}{L_o} \times 100$$

where

L_o is the original gauge length

L_x is the final gauge length

Elutriation

A test for particle size in which the speed of a liquid or gas is used to suspend particles of a desired size, with larger sizes settling for

E

removal and weighing, while smaller sizes are removed, collected, and weighed at certain time intervals.

Embeddability

The ability of a bearing material to embed harmful foreign particles and reduce their tendency to cause scoring or abrasion.

Embedded Abrasive

Fragments of abrasive particles forced into the surface of a workpiece during grinding, abrasion, or polishing.

Embossing

(1) Technique used to create depressions of a specific pattern in plastic film and sheeting. Such embossing in the form of surface patterns can be achieved on molded parts by the treatment of the mold surface with photoengraving or another process. (2) Raising a design in relief against a surface.

Embossing Die

A die used for producing embossed designs.

Embrittlement

The severe loss of *ductility* or *toughness* or both, of a material, usually a metal or alloy. Many forms of embrittlement can lead to *brittle fracture*. Many forms can occur during or thermal treatment or elevated temperature service (thermally induced embrittlement). Some of these forms of embrittlement, which affects steels, include *blue brittleness*, 885°F (475°C) *embrittlement*, *quench-age embrittlement*, *sigma-phase embrittlement*, *strain-age embrittlement*, *temper embrittlement*, *tempered martensite embrittlement*, and *thermal embrittlement*. In addition, steels and other metals and alloys can be embrittled by environmental conditions (environmentally assisted embrittlement). The forms of environmental embrittlement include *acid embrittlement*, *caustic embrittlement*, *corrosion embrittlement*, *creep-rupture embrittlement*, *hydrogen embrittlement*, *liquid metal embrittlement*, *neutron embrittlement*, *solder embrittlement*, *solid metal embrittlement*, and *stress-corrosion cracking*.

Embrittlement [885°F (475°C)]

Embrittlement of stainless steels upon extended exposure to temperatures between 400°C and 510°C (750°F and 950°F). This type of embrittlement is caused by fine, chromium-rich precipitates that segregate at grain boundaries; time and temperature directly influences the amount of segregation. Grain-boundary segregation of the chromium-rich precipitates increases strength and hardness, decreases ductility and toughness, and changes corrosion resistance. This type of embrittlement can be reversed by heating above the precipitation range.

Emery

A fine-grained, impure variety of the mineral corundum, with fine crystals of aluminum oxide embedded in a matrix of iron oxide. It usually contains only 55%–75% Al_2O_3 . The specific gravity is 3.7–4.3 and Mohs hardness about 8. It occurs as a dark-brown, granular massive mineral. It is used as an abrasive either ground into powder or in blocks and wheels. In the material, the grains are irregular, giving a varying grinding performance. The grains are graded in sizes

from 220 mesh, the finest to 20 mesh, the coarsest. *Emery paper* and cloth are usually graded from 24 to 120 mesh, and the grains are glued to one side of 9 by 11 in. (23 by 28 cm) sheets. *Flour of emery* is the finest powder, usually dust from the crushing. Emery cake is made for buffing and polishing is not likely to be made of emery but a graded combination of aluminum oxide and iron oxide, with a higher percentage of the hard aluminum oxide for buffing, and higher iron oxide for polishing.

EMF

An abbreviation for *electromotive force*.

Emission (of Electromagnetic Radiation)

The creation of radiant energy in matter, resulting in a corresponding decrease in the energy of the emitting system.

Emission Lines

Spectral lines resulting from emission of electromagnetic radiation by atoms, ions, or molecules during changes from excited states to states of lower energy.

Emission Spectrometer

An instrument that measures percent concentration of elements in samples of metals and other materials: when the sample is vaporized by an electric spark or arc, the characteristic wavelengths of light emitted by each element are measured with a diffraction grating and an array of photodetectors or photographic plates.

Emission Spectroscopy

The branch of spectroscopy treating the theory, interpretation, and application of spectra originating in the emission of electromagnetic radiation by atoms, ions, radicals, and molecules.

Emission Spectrum

An electromagnetic spectrum produced when radiation from any emitting source, excited by any of various forms of energy, is dispersed.

Emissive Electrode

A filler metal electrode consisting of a core of a bare electrode or a composite electrode to which a very light coating has been applied to produce a stable arc.

Emissivity

Ratio of the amount of energy or of energetic particles radiated from a unit area of a surface to the amount radiated from a unit area of an ideal emitter under the same conditions. It is normally necessary to specify circumstances such as wavelength, surface condition, temperature, etc.

Emulsifying Agents

Materials used to aid in the mixing of liquids that are not soluble in one another, or to stabilize the suspension of nonliquid materials in a liquid in which the nonliquid is not soluble. The suspension of droplets of one liquid in another liquid in which the first liquid is not

soluble is called an *emulsion*. The emulsion of oil and water, used in machine shops as a cutting lubricant and work coolant, may be made with soap as the emulsifying agent. The emulsifying agent protects droplets of the dispersed medium from uniting and thus separating out. The oil itself may be treated so that it is self-emulsifying. Sulfonated oils contain strong negatively charged ester sulfate groups in the molecule and do not react and conglomerate with the molecules of a weakly charged liquid. They will thus form emulsions with water without any other agent.

In emulsions of a powder in a liquid, an emulsifying agent called a *protective colloid* may be used. This is usually a material of high molecular weight such as gelatin, and such materials form a protective film around each particle of the contained powder. A photographic emulsion is a suspension of finely divided silver halide grains in gelatin. The gelatin serves as a binder, protective colloid, and sensitizer for the silver halide. The emulsion consists of 35%–40% silver halide, 60–65 gelatin, with small amounts of stabilizers, antifoggers, and hardeners. For the suspension of drug materials and pharmaceutical mixtures, *gum arabic* or *tragacanth* may be used. Starches, egg albumin, and proteins are common emulsifying agents for food preparation. *Alginates* are among the best suspending agents for a wide range of emulsions because of the numerous repelling charges in the high molecular weight and the irregular configuration of the chain, but when added to protein-containing liquids such as many foodstuffs, the similar conditions of the algin and the protein molecules cause a neutralization reaction and a precipitation of the agglomerated particles.

Sucrose esters, used as emulsifiers for foods, cosmetics, and drugs, are made from sugar and palmitic, lauric, or other fatty acids. The monoesters are soluble in water and alcohol, and the diesters are oil-soluble.

Emulsion

(1) A two-phase liquid system in which small droplets of one liquid (the internal phase) are immiscible in, and are dispersed uniformly throughout, a second continuous liquid phase (the external phase). The internal phase is sometimes described as the disperse phase. (2) A stable dispersion of one liquid in another, generally by means of an emulsifying agent that has affinity for both the continuous and discontinuous phases. The emulsifying agent, discontinuous phase, and continuous phase can together produce another phase that serves as an enveloping (encapsulating) protective phase around the discontinuous phase.

Emulsion Calibration Curve

The plot of a function of the relative transmittance of the photographic emulsion versus a function of the exposure. The calibration curve is used in spectrographic analysis to calculate the relative intensity of a radiant source from the density of a photographically recorded image.

Emulsion Cleaner

A cleaner consisting of organic solvents dispersed in an aqueous medium with the aid of an emulsifying agent.

Emulsion Inversion

An *emulsion* is said to invert when, for example, a water-in-oil emulsion changes to an oil-in-water emulsion.

Emulsion Polymerization

Polymerization of monomers dispersed in an aqueous emulsion.

Enamel

A coating that upon hardening has an enameled or glossy face. *Pottery enamels*, *ceramic enamels*, or *ceramic coatings*, and *vitreous enamels* are composed chiefly of quartz, feldspar, clay, soda, and borax, with saltpeter or borax as fluxes. The quartz supplies the silica, and such enamels are fusible glasses. In acid-resisting enamels, alkali earths may be used instead of borates. To ensure enamels opaque, opacifiers are used. They may be tin oxide for white enamel, cobalt oxide for blue, or platinum oxide for gray. Enamel-making materials are prepared in the form of a powder which is called frit. The frit-making temperature is about 2400°F (1316°C), but the enamel application temperatures are from 1400°F to 1600°F (760°C–871°C). Each succeeding coat has a lower melting point than the one before it, so as not to destroy the preceding coat. It must also have about the same coefficient of expansion as the metal to prevent cracking. Enamels for aluminum usually have a high proportion of lead oxide to lower the melting point, and enamels for magnesium may be based on lithium oxide. Some enamels for low-melting-point metals have the ceramic frit bonded to the metal with monoaluminum phosphate at temperatures as low as 400°F (204°C).

The mineral oxide coatings Fuster metals are often called *porcelain enamels*, but they are not porcelain, and the term *vitreous enamel* is preferred in the industry, although ceramic-lined tanks and pipe are very often referred to as *glass-lined steel*. Vitreous enameled metals are used for cooking, utensils, signs, chemical tanks and piping, clock and instrument dials, and siding and roofing. Thick coatings on thin metals are fragile, but thin coatings on heavy metals are flexible enough to be bent. Standard porcelain-type enamel has a smooth, glossy surface with a light reflectance of at least 65% in the white color, but pebbly surfaces that breakup the reflected image may be used for architectural applications.

High-temperature coatings may contain a very high percentage of zirconium and will withstand temperatures to 1650°F (899°C). *Refractory enamels*, for coating superalloys to protect against the erosion of hot gases to 2500°F (1371°C), may be made with standard ceramic frits to which is added boron nitride with a lithium chromate or fluoride flux. Blue undercoats containing cobalt are generally used to obtain high adhesion on iron and steel, but some of the *enameling steels* do not require an undercoat, especially when a specially compounded frit or special fluxes used. When *sodium aluminum silicate* is used instead of borax, a white finish is produced without a ground coat.

Many trade names are applied to vitreous enamels and to enameled metals. *Vitric steel* is an enameled corrugated sheet steel for construction. Cloisonné enamel is an ancient decorative enamel produced by soldering thin strips of gold on the base metal to form cells into which the colored enamel is pressed and fused into place. It requires costly hand methods and is now imitated in synthetic plastics under names such as *Enameloid*.

The word *enamel* in the paint industry refers to glossy varnishes with pigments or to paints of oxide or sulfate pigments mixed with varnish to give a glossy face. They vary widely in composition, in color and appearance, in the properties. As a class, enamels are hard and tough and offer good mar and abrasion resistance. They can be formulated to resist attack by the most commonly encountered chemical agents and corrosive atmospheres. Because of their wide range of useful properties, enamels are one of the most widely used organic finishes in industry and are especially used as household appliance finishes. The modified phenolmelamine and alkyd-melamine synthetic resins produce tough and resistant enamel coatings. Quick-drying enamels are the cellulose lacquers with pigments. Fibrous enamel, used for painting roofs, is an asphalt solution in which asbestos fibers have been incorporated. When of heavy consistency and used for caulking metal roofs, it is called *roof putty*.

E

Enameling Iron

A low-carbon, cold-rolled sheet steel, produced specifically for use as a base metal for porcelain enamel.

Enantiotropy

The relation of crystal forms of the same substance in which one form is stable above a certain temperature and the other form is stable below that temperature. For example, ferrite and austenite are enantiotropic in ferrous alloys.

Encapsulated Adhesive

An adhesive in which the particles or droplets of one of the reactive components are enclosed in a protective film (microcapsules) to prevent cure until the film is destroyed by suitable means.

Encapsulation

The enclosure of an item in plastic. Sometimes used specifically in reference to the enclosure of capacitors or circuit board modules.

End

In composites fabrication, a strand of *roving* consisting of a given number of filaments gathered together. The group of filaments is considered an end, or strand, before twisting, and a yarn after twist has been applied. An individual warp, yarn, thread, fiber, or roving.

End Clearance Angle

See *clearance angle* and also the term *face mill* and *single-point tool*.

End Count

An exact number of ends supplied on a ball of roving. See also *end*.

End Cutting-Edge Angle

The angle of concavity between the face cutting edge and the face plane of the cutter. It serves as relief to prevent the face cutting edges from rubbing in the cut. See *face mill* and *single-point tool*.

End Mark

A roll mark caused by the end of a sheet marking the roll during hot or cold rolling.

End Mill

A rotating cylindrical cutting tool with multiple cutting edges on its flat (or nearly so) end face.

End Milling

A method of machining with a rotating cutting tool with cutting edges on both the face end and the periphery. See also *face milling* and *milling*.

End Relief

Defined by the term *single-point tool*.

End Return

See preferred term *boxing*.

End-Centered

Having an atom or group of atoms separated by a translation of the type $\frac{1}{2}$, $\frac{1}{2}$, 0 from a similar atom or group of atoms. The number of atoms in an end-centered cell must be a multiple of 2.

Endothermic Atmosphere

A gas mixture produced by the partial combustion of a hydrocarbon gas with air in an endothermic reaction. Also known as endogas.

Endothermic Reaction

Designating or pertaining to a reaction that involves the absorption of heat. See also *exothermic reaction*.

End-Quench Hardenability Test

A laboratory procedure for determining the hardenability of a steel or other ferrous alloy; widely referred to as the Jominy test. Hardenability is determined by heating a standard specimen above the upper critical temperature, placing the hot specimen and a fixture so that a stream of cold water impinges on one end, and, after cooling to room temperature is completed, measuring the hardness near the surface of the specimen at regularly spaced intervals along its length. The data are normally plotted as hardness versus distance from the quenched end. See the term *Jominy test*.

Endurance

The capacity of a material to withstand repeated application of stress.

Endurance Limit

(1) The maximum stress that a material can withstand for an infinitely large number of fatigue cycles. See also *fatigue limit* and *fatigue strength*. (2) An endurance limit may also be specified in the case of steels subjected to stresses which exceed their fatigue limit. See *fatigue*.

Endurance Ratio

(1) The ratio of the *endurance limit* for completely reversed flexural stress to the tensile strength of a given material. (2) The ratio of fatigue limit to ultimate tensile strength. For ferritic steels of U.T.S. up to about 1100 MPa (75 T/in.²) it is approximately 0.5. See *fatigue*.

Energy Barrier

See *potential barrier*.

Energy Trough

See *potential barrier*.

Energy-Dispersive Spectroscopy (EDS)

A method of x-ray analysis that discriminates by energy levels the characteristic x-rays emitted from the sample. Compare with *wave-lengths-dispersive spectroscopy*.

Engine Oil

An oil used to lubricate an internal combustion engine.

Engineering Adhesive

A bonding agent intended to join metal, plastics, wood, glass, ceramics, or rubber. The term differentiates such bonding agents from glues used to join paper and other nondurables.

Engineering Ceramics

Same as *advanced ceramics*.

Engineering Films

Specific properties that separate engineering films from their commodity counterparts include greater tensile and impact strength; improve moisture and gas barrier characteristics; good heat resistance and weatherability; better bonding and lamination; and improved electrical ratings. One or more of these properties can be obtained by choosing from a number of different polymer films.

Several melt-processable engineering thermoplastic films such as oriented polyester, oriented nylon, and unoriented nylon, exhibit high strength, especially at high temperatures. In addition, they provide toughness at low temperatures, stiffness and abrasion resistance, and good chemical resistance. Polyester film is made from the PET polymer. The monomer is polymerized, extruded, cast into a web, and biaxially oriented, forming a drawn polyester film.

Oriented polypropylene, a thermoplastic with low specific gravity, has excellent resistance, relatively high melting point, and good strength. Polycarbonate film is specified for its toughness, clarity, and high heat-deflection temperature.

Polyimides, both thermoplastics and thermosets, retain their principal properties over a wide temperature range. They have useful mechanical properties, even at cryogenic temperatures. At -162°C , the film can be bent around a 6.4-mm mandrel without breaking and, at 500°C , its tensile strength is 31 MPa. Room-temperature mechanical properties are comparable to those of polyester film.

To minimize transmission of moisture vapors, fluoropolymers are the best choice. This family of material has a general paraffinic structure with some or all of the hydrogen atoms replaced by fluorine.

Polyetheretherketone (PEEK), a high-performance thermoplastic, offers outstanding thermal properties as well as resistance to many solvents and proprietary fluids. This film can be used for interbonding or cladding in PEEK structural components. Thermoplastic and thermoset acrylics are noted for exceptional clarity and weatherability, and also offer favorable stiffness, density, chemical resistance, and toughness.

Plastic film can be manufactured from almost any resin, but not every resin produces an engineering film. Generally, the properties of a resin-based film are related to the chemistry of the basic polymer; however, properties may be further affected by subsequent processing techniques. Manufacturers can choose from, and end users can specify, a range of process treatments that significantly enhance heat stability, mechanical properties, electrical characteristics, barrier properties, and bondability.

Coatings are typically applied by emulsion, solvent, and dry methods. Results vary according to the formula used: PVDC coatings improve barrier properties; polyurethane improves abrasion resistance; and aluminum coatings alter electrical characteristics.

Some processors have developed proprietary antistatic coatings that are cured by electron-beam radiation. Metal coatings produce conductive capabilities and also enhance barrier properties. Often, metallization is used to improve moisture-barrier properties for biaxially oriented nylon and polypropylene.

Surface treatment, which removes low-molecular-weight residue, improves adhesion and appearance. Several methods may be used. Corona discharge techniques position the film between an electrically grounded roller and a high-voltage electrode. A continuous-arc discharge (corona) is generated to clean and activate the film surface.

In gas-plasma surface treatments, film is placed in a reaction chamber. After evacuation, the chamber is charged with O_2 , A, helium, or N_2 , while a radiofrequency field ionizes the gas. A resultant glow discharge creates free radicals on the surface, in adhesion.

Engineering Plastics

A general term covering all plastics, with or without fillers or reinforcements, that have mechanical, chemical, and thermal properties suitable for use as construction materials, machine components, and chemical processing equipment components. Included are acrylonitrile-butadiene-styrene, acetal, acrylic, fluorocarbon, nylon, phenoxy, polybutylene, polyaryl ether, polycarbonate, polyether (chlorinated), polyether sulfone, polyphenylene oxide, polysulfone, polyimide, rigid polyvinyl chloride, polyphenylene sulfide, thermoplastic urethane elastomers, and many other reinforced plastics.

Engineering Steels

In the United Kingdom, steels have a six-character designation comprising three initial digits, a letter and two final digits, for example, 080M40. These designations indicate, with some anomalies and to a limited extent, the type of steel, its condition of supply and its composition. The first three digits indicate alloy type. The fourth character, a letter, indicates the condition of supply. The final digits indicate for most grades except the austenitics the mean of the carbon content range.

Engineering Strain (e)

A term sometimes used for average linear strain in order to differentiate it from *true strain*. In tension testing, it is calculated by dividing the change in the gauge length by the original gauge length.

Engineering Stress (s)

A term sometimes used for conventional stress in order to differentiate it from *true stress*. In tension testing, it is calculated by dividing the breaking load applied to the specimen by the original cross-sectional area of the specimen.

Engler Viscosity

A commercial measure of viscosity expressed as the ratio between the time in seconds required for 200 cm^3 of a fluid to flow through the orifice of an Engler viscometer at a given temperature under specified conditions and the time required for 200 cm^3 of distilled water at 20°C (70°F) to flow through the orifice under the same conditions.

E

Engobe

A slip coating applied to a ceramic body for imparting color, opacity, or other characteristics, and subsequently covered with a glaze.

Enthalpy

The total internal and external energy content of a system.

Entraining Velocity

The velocity of a liquid at which bubbles of gas are carried along in the strain.

Entropy

The thermodynamic measure of the state of disorder in a system.

Entry Mark (Exit Mark)

A slight corrugation caused by the entry or exit rolls of a *roller leveling unit*.

Environment

The aggregate of all conditions (such as contamination, temperature, humidity, radiation, magnetic and electric fields, shock, and vibration) that externally influence the performance of a material or component.

Environmental Cracking

Brittle fracture of a normally ductile material in which the corrosive effect of the environment is a causative factor. Environmental cracking is a general term that includes *corrosion fatigue*, *high-temperature hydrogen attack*, *hydrogen blistering*, *hydrogen embrittlement*, *liquid metal embrittlement*, *solid metal embrittlement*, *stress-corrosion cracking*, and *sulfide stress cracking*. The following terms have been used in the past in connection with environmental cracking, but are becoming obsolete: caustic embrittlement, delayed fracture, season cracking, static fatigue, stepwise cracking, sulfide corrosion cracking, and sulfide stress-corrosion cracking. See also *embrittlement*.

**Environmental Stress Cracking
(alternatively, Stress Cracking)**

Cracking occurring as a result of the effect of a corrosive environment and stress acting concurrently. This term is common with reference to polymeric plastic materials but is occasionally used in the case of metals as an alternative to stress corrosion. The stress may be externally imposed or it may be residual from manufacturing operations.

Environmentally Assisted Embrittlement

See *embrittlement*.

Epitaxis/Epitaxy

(1) The growth of a new crystal at the surface of a pre-existing crystal where the lattice orientation of the new crystal is dictated, across the intervening boundary, by the lattice of the preexisting crystal. (2) Growth of electrodeposit or vapor deposit in which the

orientation of the crystals in the deposit are directly related to crystal orientations in the underlying crystalline substrate.

Epichlorohydrin

The basic epoxidizing resin intermediate in the production of epoxy resins. It contains an epoxy group and is highly reactive with polyhydric phenols such as bisphenol A.

Epoxide

Compound containing the oxirane structure, a three-member ring containing two carbon atoms and one oxygen atom. The most important members are ethylene oxide and propylene oxide.

Epoxy Plastic

A thermoset polymer containing one or more epoxide groups and curable by reaction with amines, alkyl mells, phenols, carboxylic acids, acid anhydrides, and mercaptans. An important matrix resin in reinforced composites and in structural adhesives.

Epoxy Resins

Epoxy (Ep) resins comprise an extremely broad and diverse family of materials. They are used in the form of protective coatings, adhesives, reinforced plastics, molding compounds, casting and potting compounds, and foams.

Epoxies, perhaps best known as adhesives, are premium thermosetting plastics, and are generally employed in high-performance uses where their high cost is justified. They are available in a wide variety of forms, both liquid and solid, and are cured into the finished plastic by a catalyst or with partners containing active H₂. Depending on the type, they are cured at either room temperature or elevated temperatures.

Liquid epoxies are used for casting, for potting or encapsulation, and for laminating. They are used unfilled or with any of a number of different mineral or metallic powders. Molding compounds are available as liquids, and also as powders with various types of fillers and reinforcements.

Properties

The epoxy resins have very high adhesion to metals and nonmetals, heat resistance from 177°C to 260°C, dielectric strength to 22 V/m, and hardness to Rockwell M110. The tensile strength may be up to 82 MPa, with elongation to 2%–5%, but some resilient encapsulating resins are made with elongation to 150% with lower tensile strengths. The resins have high resistance to common solvents, oils, and chemicals.

An unlimited variety of epoxy resins is possible by varying the basic reactions with different chemicals or different catalysts, or both, by combination with other resins, or by cross-linking with organic acids, amines, and other agents. To reduce costs when used as laminating adhesives, they may be blended with furfural resins, giving adhesives of high strength and high chemical resistance. Blends with polyamides have high dielectric strength, mold well, and are used for encapsulating electrical components. By using a polyamide curing agent, an epoxy can be made water emulsifiable for use in water-based paints. An epoxy resin with 19% bromine in the molecule is flame-resistant. Another grade, with 49% bromine, is a semisolid, used for heat-resistant adhesives and coatings.

The epoxies have excellent electrical, thermal, and chemical resistance. Their strength can be further increased with fibrous reinforcement or mineral fillers. The variety of combinations of epoxy resins and reinforcements provides a wide latitude in properties obtainable in molded parts.

Molded epoxy parts are hard, rigid, relatively brittle, and have excellent dimensional stability over a broad temperature range. Some fiber-reinforced formulations can withstand service temperatures above 206°C for brief periods. Their excellent electrical properties, in combination with high mechanical strength, qualify them for electrostructural applications. Resins based on bisphenol-A are adequate for most services. However, cycloaliphatics are recommended for parts subjected to arcing conditions or those requiring outdoor weatherability, see Table E.2.

Excellent adhesion in structural applications is another outstanding property of epoxy systems. Epoxy adhesives for bonding many dissimilar materials can be supplied either as one- or two-part systems. One-part systems require heat for curing; two-part systems usually cure at room temperature, but properties are improved when the materials are heat-cured. Some epoxy adhesive systems can withstand temperatures to 232°C, although properties at such temperatures are considerably lower than at room temperature.

Applications

- Casting resins are primarily used for potting or encapsulating electrical or electronic equipment. The excellent adhesion and extremely low shrinkage of the epoxies,

coupled with their high dielectric properties, provide a well-sealed, voidless, well-insulated component.

- Foaming resins have also been used for electronic potting.
- Liquid resins are also formulated with a variety of fillers, such as metal powder, to provide effective patching and repair putties or pastes. Such compounds can be used to patch both metal and plastic surfaces.
- Liquid resin systems are used to produce low-pressure reinforced laminates and moldings, high-pressure industrial thermosetting laminates (NEMA Grade G-10 glass cloth base, as well as paper-based laminates for electrical uses), and filament wound shapes.
- Epoxy laminates are also widely used in plastic tools. They are used for drilling, checking, and locating fixtures, where dimensional accuracy is critical. They are also used to provide durable surfaces for metal-forming tools, such as draw dies for short-run production.
- Filament wound structures are used for such applications as rocket-motor booster cases, pressure vessels, and chemical tanks and pipe.
- Molding compounds provide the performance characteristics of epoxy resins with the automated speed and economy of compression and transfer molding. They are being used primarily for electrical components.

Handling and Resin Selection

Because the cure of an epoxy is brought about by a chemical reaction, and not by a simple process of solvent evaporation, it is quite

TABLE E.2
Properties of Epoxies

ASTM Test	Property	Casting Resins				
		Molding Compounds		Bisphenol A		
		Glass Fiber Filler	Mineral Filler	No Filler	Silica Filler	Cycloaliphatic
<i>Physical</i>						
D792	Specific gravity	1.6–2.0	1.6–3.0	1.11–1.40	1.6–2.0	1.16–1.21

E

important that users recognize at the outset that handling (particularly for the two-component, low-temperature curing compounds) requires more care than that of older materials. However, because this is, and probably will be, a problem for some time to come, procedures have been developed that keep difficulties in handling to a minimum. One simple and inexpensive way of eliminating frequent weighing is to use calibrated mixing containers where it is necessary only to fill to the first calibration with the base, to the second with a hardener, mix, and apply.

Formulators meet this problem by supplying the compounds packaged in preweighted containers, while equipment manufacturers use automatic mixers and dispensers. It is possible through the use of these machines to eject preweighted and premixed shots of compound as the operator requires.

One-component systems, as the name indicates, eliminate problems of weighing, mixing, and pot life, and are subdivided into solids, most often "B" staged epoxy powders, and liquids containing latent hardeners such as boron trifluoride, or anhydride/solvent solutions.

Powders have been used to some extent as adhesives and in potting, but are employed most widely for the fluidized-bed coating method or in compression and transfer molding. The epoxy fluidized-bed approach provides a relatively easy way of applying encapsulant coatings in uniform thickness over contours but is not suitable for impregnation, or for coating units that cannot be heated.

In resin selection, epoxy compounds can be categorized (although there are exceptions) as (1) two-component liquids that will cure at temperatures from 21.1°C to 60°C, but that have short pot lives; (2) two-component liquid systems requiring cure at temperatures up to 177°C, but that offer longer pot lives and improved operational characteristics; and (3) one-component liquids and powders that reduce handling problems, offer optimum operating characteristics, but that require higher curing temperatures (in the range of 177°C–204°C).

With respect to possible methods of application, with the exception of the powders, epoxies are supplied for use by spray, brush, spatula, roller coat, knife coat, dipping, filament winding, laminating, and casting. All these except casting are self-descriptive and this is simply the method of producing a defined shape by pouring a compound into a mold where it cures and from whence it can later be removed. On the other hand, if an object has been placed in the mold and epoxy cast around it, the process is called potting.

Epoxy Smear

See *resin smear*.

Epsilon (Ε)

Designation generally assigned to intermetallic, metal-metalloid, and metal-nonmetallic compounds found in ferrous alloy systems, for example, Fe_3Mo_2 , FeSi , and Fe_3P .

Epsilon Carbide

Carbide with hexagonal close-packed lattice that precipitates during the first stage of tempering of primary martensite. Its composition corresponds to the empirical formula $\text{Fe}_{2.4}\text{C}$.

Epsilon Structure

Structurally analogous close-packed phases or electron compounds that have ratios of seven valence electrons to four atoms.

Equator

In *filament winding* of composites, the line in a pressure vessel described by the junction of a cylindrical portion and the end dome. Also called tangent line or point.

Equiaxed Grain Structure

A structure in which the grains have approximately the same dimensions in all directions.

Equicohesive Temperature

The temperature at which damage development within grains is matched by that at grain boundaries for a given strain rate. Above this temperature, a material fails in an intergranular mode, below in a transgranular mode.

Equilibrium

The dynamic condition of physical, chemical, mechanical, or atomic balance that appears to be a condition of rest rather than one of change.

Equilibrium Centrifugation

In resinography, a method for determining the distribution of a molecular weight by spinning a solution of the specimen at a speed such that the molecules of the specimen are not removed from the solvent but are held at a point where the (centrifugal) force tending to remove them is balanced by the dispersive forces caused by thermal agitation.

Equilibrium Diagram

A graph of the temperature, pressure, and composition limits of phase fields in an alloy system as they exist under conditions of thermal dynamical equilibrium. In metal systems, pressure is usually considered constant. Compare with *phase diagram*.

Equilibrium (Reversible) Potential

The *potential* of an electrode in an electrolytic solution when the forward rate of a given reaction is exactly equal to the reverse rate. The equilibrium potential can only be defined with respect to a specific electrochemical reaction.

Equilibrium Segregation

The tendency for solute atoms in a solid solution to diffuse to particular sites such as grain boundaries. This may result in depletion of the solute in the near grain boundary regions. See *solution*.

Equivalent/Equivalence Factor

Various factors applied to alloying elements to allow comparison of their relative effect on some aspect such as microstructure or hardenability. See carbon equivalent for example.

Equivalent Radial Load

The level of constant radial load on a rolling-element bearing that, when the bearing is stationary with respect to the outer race, will produce the same rating life as a given combination of radial and thrust loads under the same conditions of operation.

Equivalent Section/Round

In the context of hardenability of steel, the circular section equivalent to the noncircular section under consideration.

Equivalent Weight

The mass of a substance that will react, directly or indirectly, with unit mass of hydrogen.

Erg

The unit of energy in the non-SI metric (centimeter-gram-second) system; it is the work done by a force of one dyne moving 1 cm. $1 \text{ erg} = 10^{-7} \text{ J}$.

Erichson (Cupping) Test

A test for determining the ductility of sheet metal particularly for cupping or deep drawing applications. The sheet under test is held by an outer ram against a die face having a central hole. A ball-ended cone plunger on an inner ram is then forced into the sheet until a crack appears. The high, in millimeters, of the cup at crack initiation is a measure of ductility.

Erosion

(1) Loss of material from a solid surface due to relative motion in contact with a fluid that contains solid particles. Erosion in which the relative motion of particles is nearly parallel to the solid surface is called *abrasive erosion*. Erosion in which the relative motion of the solid particles is nearly normal to the solid surface is called *impingement erosion* or impact erosion. (2) Progressive loss of original material from a solid surface due to mechanical interaction between that surface and a fluid, a multicomponent fluid, and impinging liquid, or solid particles. (3) Loss of material from the surface of an electrical contact due to an electrical discharge (arcing). See also *cavitation erosion*, *electrical pitting*, and *erosion-corrosion* and *cavitation*.

Erosion (Brazing)

A condition caused by dissolution of the base metal by molten filler metal resulting in a postbrazing reduction in the thickness of the base metal.

Erosion Rate

Any determination of the rate of loss of material (erosion) with exposure duration. And certain contexts (e.g., ASTM erosion tests), it is given by the slope of the cumulative erosion–time curve.

Erosion Rate-Time Curve

A plot of instantaneous erosion rate versus exposure duration, usually obtained by numerical or graphical differentiation of the cumulative erosion–time curve.

Erosion-Corrosion

A conjoint action involving *corrosion* and *erosion* in the presence of a moving corrosive fluid, leading to the accelerator loss of material.

Erosive Wear

See *erosion*.

Erosivity

The characteristic of a collection of particles, liquid stream, or a slurry that expresses its tendency to cause erosive wear when forced against a solid surface under relative motion.

Error

Deviation from the correct value. In the case of a testing machine, the difference obtained by subtracting the load indicated by the calibration device from the load indicated by the testing machine.

Escape Peak

An artifact observed in x-ray analysis; manifested as a peak at energy 1.74 keV (the silicon $K\alpha$ Peak) less than the major line detected. Escape peaks can be avoided by increasing the accelerating voltage.

Esters

Combination of alcohols with organic acids, which form several important groups of commercial materials. The esters occur naturally in vegetable and animal oils and fats as combinations of acids with the alcohol glycerin. The natural fats are usually mixtures of esters of many acids, coconut oil having no less than 14 acids. Stearic, oleic, palmitic, and linoleic acid esters are the common bases for most vegetable and animal fats, and the esters of the other acids such as linolenic, capric, and arachidic give the peculiar characteristics of the particular fat, although the physical characteristics and melting points may be governed by the basic esters. Esters occur also in waxes, the vegetable waxes being usually found on the outside of leaves and fruits to protect them from loss of water. The waxes differ from the fats in that they are combinations of monacids with monohydric, or simple, alcohols rather than with glycerin. They are harder than fats and have higher melting points. Esters of still lower molecular weights are also widely distributed in the essential oils of plants where they give the characteristic odors and tastes. All the esters have the characteristic formula ArCOOR or RCOOR , where R represents an *alkyl group*, and Ar an *aryl group*, that is, where R is a univalent straight-chain hydrocarbon and Ar is a univalent benzene ring. In the esters of low molecular weight that make the odors and flavors, the combination of different alcohols with the same acid yields oils of different flavor. Thus the ester methyl acetate is *peppermint oil*; amyl acetate is banana oil; and isoamyl acetate is *pear oil*. Esters are used as solvents, flavors, perfumes, waxes, oils, fats, fatty acids, pharmaceuticals, and in the manufacture of soaps and many chemicals. Ester liquid lubricants have good heat and oxidation resistance at high temperatures and good fluidity at low temperatures. They are widely used in jet aircraft.

The natural esters are recovered by pressing or extraction, and steam distillation. Synthetic esters are prepared by reacting an alcohol with an organic acid in the presence of a catalyst, such as sulfuric acid or *paratoluenesulfonic acid*. The product is purified with an azeotrope,

E

such as benzene or toluene. A range of *cellulose acetate esters* are made by esterification of cellulose with acetate anhydride. *Cellulose nitrate ester* is obtained by reacting cellulose with nitric acid, *cellulose sulfate* from *chlorosulfonic acid* in pyridine solvent, and *cellulose phosphate* from phosphoric acid in the molten urea. *Alkoxysilanes* are silicon esters in which the silicon is connected to an organic group by oxygen.

Esther alcohols are intermediates that require less acid for esterification.

Estimate

This particular value, or values, of a parameter computed by an estimation procedure for a given sample.

Estimation

A procedure for making a statistical inference about the numerical values of one or more unknown population parameters from the observed values in a sample.

Etch Cleaning

Removing soil by dissolving away some of the underlying metal.

Etch Figuring

In metallography, deliberate etching to an extent that would normally be excessive to produce a pattern of pitting which reveals some feature of interest. Such features may be on a microscale, for example, the facets of the pits can reflect crystallographic planes, or on a macroscale as the distribution of pitting can indicate bulk segregation or flow.

Etch Pits

Pitting resulting from excessive etching unless etch figuring is intended.

Etch Rinsing

Pouring etchant over a tilted surface until the desired degree of attack is achieved. Use for excellence with severe gas formation.

Etchant

(1) A chemical solution used to etch a metal to reveal structural details. (2) A solution used to remove, by chemical reaction, the unwanted portion of material from a printed circuit board. (3) Hydrofluoric acid or other agents used to attack the surface of glass for marking or decoration.

Etched Metal Mask

A mask formed by etching apertures through a solid metal protected by a photo resist.

Etching

(1) Subjecting the surface of a metal to preferential chemical or electrolytic attack in order to reveal structural details for metallographic examination. (2) Chemically or electrochemically removing tenacious films from a metal surface to condition the surface for a subsequent treatment, such as painting or electroplating. (3) A process by

which a printed pattern is formed on a printed circuit board by either chemical or chemical and electrolytic removal of the unwanted portion of conductive material bonded to a base. (4) Unless otherwise specified, the term usually implies chemical attack in a liquid. Other techniques include *electrochemical dissolution*, *selective oxidation in air at elevated temperature*, and *ion bombardment*.

Etching Materials

These are chemicals, usually acids, employed for cutting into, or etching, the surface of metals, glass, or other material. In the metal industries, they are called etchants. The usual method of etching is to coat the surface with a wax, asphalt, or other substance not acted upon by the acid; cut the design through with a sharp instrument; and then allow the acid to corrode or dissolve the exposed parts. For etching steel, a 25% solution of H_2SO_4 in water or an FeCl_3 solution may be used. For etching stainless steel a solution of FeCl_3 and HCl in water is used. For high-speed steels, brass, or nickel, a mixture of HNO_3 and HCl acids in water solution is used, or nickel may be etched with a 45% solution of H_2SO_4 . Copper may be etched with a solution of HCrO_3 acid. Brass and nickel may be etched with an acid solution of FeCl_3 and KClO_3 . For red brasses, deep etching is done with concentrated HNO_3 acid mixed with 10% HCl acid, with the latter added to keep the SnO_2 in solution and thus retain a surface exposed to the action of the acid. For etching aluminum, a 9% solution of CuCl_2 and 1% acetic acid, or a 20% solution of FeCl_3 may be used, followed by a wash with strong HNO_3 acid. NaOH , NH_4OH , or any alkaline solutions are also used for etching aluminum. Zinc is preferably etched with weak HNO_3 acid, but requires a frequent renewal of the acid. Strong acid is not used because of the heat generated, which destroys the wax coating. A 5% solution of HNO_3 acid will remove 0.005 cm of zinc/min compared with the removal of over 0.013 cm/min in most metal-etching processes. Glasses etch with HF acid or with white acid. White acid is a mixture of HF acid and ammonium bifluoride, a white crystalline material of the composition $(\text{NH}_4)\text{FHF}$.

The process in which the metal is removed chemically to give the desired finish as a substitute for mechanical machining is called chemical machining.

Ether

Ether is the common name for ethyl ether, or diethyl ether, a highly volatile, colorless liquid made from ethyl alcohol. It is used as a solvent for fats, greases, resins, and nitrocellulose, and in medicine as an anesthetic. The specific gravity is 0.720, and its vapor is heavier than air and is explosive.

Recently, the promotion for the production and use of cleaner-burning fuels was announced. As a result, methyl tertiary butyl ether (MTBF) became a very important petrochemical. MTBF is the most widely produced ether for oxygenates. It is commonly produced by the dehydrogenation of isobutane and the subsequent reaction of isobutylene with methanol.

Ethyl Silicate

A strong bonding agent for sand and refractories used in preparing molds in the investment casting process.

Ethylene Plastics

Plastics based on polymers of ethylene or copolymers of ethylene with other monomers, the ethylene being in greatest amount by mass.

Ethylene-Propylene Elastomer

Ethylene-propylene elastomer is a completely saturated copolymer made by solution polymerization. The remarkable properties of the material include exceptional ozone resistance, excellent electrical properties, good high- (149°C–163°C) and low-temperature properties, good stress-strain characteristics, and resistance to chemicals, light, and other types of aging.

Ethylene-propylene rubber has required a peroxide or peroxide-sulfur modified curing system. Sulfur improves the peroxide curing efficiency and assists in chemical cross-linking of the polymer chains, thereby importing better physical properties to the vulcanizate.

Some plasticizers used in other rubbers are not suitable for ethylene-propylene rubber. Most acceptable plasticizers are saturated materials of relatively low polarity such as paraffinic hydrocarbon oils and waxes.

Euler Angles

In crystallographic texture analysis, three angular parameters that specify the orientation of a body with respect to reference axes.

Eutectic

(1) An isothermal reversible reaction in which a liquid solution is converted into two or more intimately mixed solids on cooling, the number of solids formed being the same as a number of components in the system. (2) An alloy having the composition indicated by the eutectic point on a phase diagram. (3) An alloy structure of intermixed solid constituents formed by a eutectic reaction often in the form of regular arrays of lamellae or rods. (4) A eutectic is an intimate mixture of two solid solutions formed, on solidifying from a single liquid solution, at the eutectic temperature. Metals mixed together in different ways in both the liquid and the solid states. One simple case where two metals, A and B, are completely soluble in each other.

Eutectic Arrest

In a cooling or heating curve, an approximately isothermal segment corresponding to the time interval during which the heat transformation from the liquid phase to two or more solid phases is evolving.

Eutectic Bonding

The forming of a bond by bringing two solids to their lowest constant melting point at which the molten solids mix and become hard upon cooling.

Eutectic Carbides

Carbide formed during freezing as one of the mutually insoluble phases participating in the eutectic reaction of a hypereutectic tool steel. See also *hypereutectic alloy*.

Eutectic Melting

Melting of localized microscopic areas whose composition corresponds to that of the eutectic in the system.

Eutectic Point

The composition of a liquid phase in univariant equilibrium with two or more solid phases; the lowest melting alloy of a composition series.

Eutectic-Cell Etching

Development of eutectic cells (grains).

Eutectoid

(1) An isothermal reversible reaction in which a solid solution is converted into two or more intimately mixed solids on cooling, the number of solids formed being the same as the number of components in the system. (2) An alloy having composition indicated by the eutectoid point on a phase diagram. (3) An alloy structure of intermixed solid constituents formed by a eutectoid reaction.

Eutectoid Point

The composition of a solid phase that undergoes univariant transformation into two or more other solid phases upon cooling.

Evaporation

The vaporization of a material by heating, usually in a vacuum. In electron microscopy, this process is used for shadowing or to produce thin support films by condensation of the vapors of metals or salts.

Evaporative Deposition

The techniques of condensing a thin film of material on a substrate. The entire process takes place in a high vacuum. The source material may be radioactively heated by bombardment with electrons (electron beam) or may be heated by thermal-conduction techniques.

Even Tension

In composite reinforcing fibers, the process whereby each end of roving is kept in the same degree of tension as the other ends making up that ball of roving. See also *catenary*.

Ewald Sphere

In electron diffraction theory, a geometric construction, of radius equal to the reciprocal of the wavelength of the incident radiation, with its surface at the origin of the reciprocal lattice. Any crystal plane will reflect if the corresponding reciprocal lattice point lies on the surface of this sphere.

Exchange Current

When an electrode reaches dynamic equilibrium in a solution, the rate of anodic dissolution balances the rate of cathodic plating. The rate at which either positive or negative charges are entering or leaving the surface at this point is known as the exchange current.

Exchange Current Density

The rate of charge transfer per unit area when an electrode reaches dynamic equilibrium (at its reversible potential) in a solution; that is, the rate of anodic charge transfer (oxidation) balances the rate of cathodic charge transfer (reduction).

E

Excitation Index

In materials characterization, the ratio of the intensities of two selected spectral lines of an element having widely different excitation energies. This ratio serves to indicate the level of excitation energy in the source.

Excitation Potential (X-Ray)

The applied potential on an x-ray tube required to produce characteristic radiation from the target.

Excitation Volume

The volume within the sample in which data signals originate.

Exfoliation

Corrosion that proceeds laterally from the sites of initiation along planes parallel to the surface, generally at grain boundaries, forming corrosion products that force metal away from the body of the material, giving rise to a layered appearance.

Exogenous Inclusion

An *inclusion* that is derived from external causes. Slag, draws, entrapped mold materials, and refractories are examples of inclusions that would be classified as exogenous. In most cases, these inclusions are macroscopic or visible to the naked eye. Compare with *indigenous inclusion*.

Exotherm

The temperature/time curve of a chemical reaction or a phase change giving off heat, particularly the polymerization of casting resins. The amount of heat given off. The term has not been standardized with respect to sample size, ambient temperature, degree of mixing, and so forth.

Exothermic

Characterized by the liberation of heat.

Exothermic Atmosphere

A gas mixture produced by the partial combustion of a hydrocarbon gas with air in an exothermic reaction. Also known as *exogas*.

Exothermic Reaction

A reaction that liberates heat, such as the burning of fuel or when certain plastic resins are cured chemically.

Expandable Plastic

A plastic that can be made cellular by thermal, chemical, or mechanical means. Foam plastics such as expandable polystyrene and foamed polyurethane are examples.

Expanded Metal

Sheet metal that has been slit and expanded to form a mesh, which is used for reinforced-concrete work or plaster wall construction, and for making grills, vents, and such articles as trays, where stiffness is needed with light weight. The expanded metal has greater rigidity than the original metal sheet and permits welding of the concrete or plaster through the holes. It is made either with a plain diamond-shape mesh or with rectangular meshes. One type is made by slitting the sheet and stretching the slits into the diamond shape. The other variety is made by pushing out and expanding the metal in the meshes so that the flat surface of the cut strand is nearly at right angles to the surface of the sheet. Expanded metal is made from low-carbon steel, iron, or special metals. It is also marketed as *metal lath*, usually 2.5 m long and 0.4–0.5 m wide. *Rigidized metal*, or *textured metal*, is thin sheet that is not perforated, but has the designs rolled into the sheet so that the rigidity of the sheet is increased two to four times. Thus, extremely thin sheets of stainless steel can be made for novelties, small mechanical products, and paneling. *Perforated metals* are sheet metals with the perforations actually blanked out of the metal. They are marketed and sheets of carbon steel, stainless steel, or Monel metal, with a great variety of standard designs those with round, square, diamond, and rectangular designs are used for screens and for construction. *Agaloy* is perforated metal made into tube form.

Expanding

A process used to increase the diameter of a cup, shell, or tube. See also *bulging*.

Expansion

(1) An increase in size of a powder metallurgy compact, usually related to an increase in temperature. A decrease in temperature produces an opposite effect. (2) Sometimes used in mean growth.

Expansion Film

An *interference* or *force fit* made by placing a cold (subzero) inside member into a warmer outside member and allowing an equalization of temperature.

Expansive Metal

An alloy that expands on cooling from the liquid state. The expansive property of certain metals is an important characteristic in the production of accurate castings having full details of the mold such as type castings. The alloys are also used for proof-casting of forging dies, for sealing joints, for making duplicates of master patterns, for holding die parts and punches in place, and for filling defects in metal parts in castings. Antimony and bismuth are the metals most used to give expansion to the alloys.

Expendable Pattern

A pattern that is destroyed in making a casting. It is usually made of wax (*investment casting*) or expanded polystyrene (hot foam casting).

Explosion Welding

A solid-state welding process affected by a controlled detonation, which causes the parts to move together at high velocity. The resulting bond zone has a characteristic wavy appearance.

Explosive

A material that, upon application of a blow or by rise in temperature, is converted in a small space of time to other compounds more stable and occupying much more space. Commercial explosives are solids or liquids that can be instantaneously converted by friction, heat, shock, or spark to a large volume of gas, thereby developing a sudden rise in pressure which is utilized for blasting or propelling purposes. *Gunpowder* is the oldest form of commercial or military explosive, but this has been replaced for military purposes by more powerfully acting chemicals. *Smokeless powder* was a term used to designate nitrocellulose powders as distinguished from the smoky black gunpowder. *Blasting powders* are required to be relatively slow-acting to have a heaving or rending effect. Military explosive used as propellants must not give instantaneous detonation, which would burst the gun, but are arranged to burn slowly at first and not reach a maximum explosion until the projectile reaches the muzzle. This characteristic is also required in explosives used for the explosive forming of hard metals. The more rapid acting high explosives are generally used for bombs, torpedoes, boosters, and detonators. The *detonators* are extremely sensitive explosives, such as the fulminates, set off by a slight blow but too sensitive to be used in quantity as a charge. The *booster explosives* are extremely rapid but not as sensitive as the detonators. They are exploded by the detonators used and in turn set off the main charge of explosive. Some explosives such as nitroglycerin can be exploded by themselves, while others require oxygen carriers or carbon carriers mixed with them. In combination with *nitrocellulose*, it is the principal component of powders and solid rocket propellants. Together with *nitroglycol*, it is the major constituent of gelatinous industrial explosives. Other requirements of explosives are that they not react with the metal container, be stable at ordinary temperatures, and not decompose easily in storage or on exposure to air.

Shaped charges of high explosive give a penetrating effect, known as the *Monroe effect*, used in armor-piercing charges. A solid mass of explosives spends itself as a flat blast; but with a conical hole in the charge, and having the open end facing the target, a terrific piercing effect is generated by the converging detonation waves coming from the sides of the column. This effect drives a jet of hot gases through the steel armor.

Trinitrotoluene, or *trinitrotoluol*, also commonly known as TNT is the principal constituent of many explosives. It is safe in handling because it does not detonate easily but is exploded readily with mercury fulminate and is used for shrapnel, hand grenades, mines, and depth bombs. TNT is made by the titration of toluol with nitric and sulfuric acids.

Explosive Compacting

See *high-energy-rate compacting*.

Explosive Forming

The shaping of metal parts in which the forming pressure is generated by an explosive charge that takes the place of the punch in conventional forming. A single-element die is used with the blank held over it, and the explosive charge is suspended over the blank at a predetermined distance (standoff distance). The complete assembly is often immersed in a tank of water. See also *high-energy-rate forming*.

Exposed Underlayer

In composites fabrication, the underlying layer of mat or roving not covered by surface mat in a protrusion. This condition can be caused by reinforcement shifting, too narrow a surface mat, too wide an

underlying mat, uneven slitting of the surface mat, necking down of the surface mat, or excessive tension in pulling the surface mat off the spindle.

Exposure

The product of the intensity of a radiant source in the time of irradiation.

Extend

The addition of fillers or low-cost materials to plastic resins as an economy measure. To add inert materials to improve void-filling characteristics and reduce crazing.

Extended X-Ray Absorption Fine Structure (EXAFS)

The weak oscillatory structure extending for several hundred electron volts away from an absorption edge. The oscillations occur because the electromagnetic wave produced by the ionization of the absorbing atom for some energy E has a wavelength $\lambda = 1.225/(E - E_k)^{1/2}$ nm, where E_k is the energy of the absorption edge. For example, a loss of 100 eV above an edge corresponds to a wavelength of 0.12 nm, which is of the order of atomic spacing. Consequently, the wave can be diffracted from neighboring atoms and return to interfere with the outgoing wave. An analysis of EXAFS data reveals important information about atomic arrangements and bonding. Either synchrotron x-radiation or the electron beam in the analytical transmission electron microscope can be used as the excitation source. See also *analytical electron microscopy* and *synchrotron radiation*.

Extenders

(1) Low-cost materials used to dilute or extend high-cost resins without significant lessening of properties. (2) Substances, generally having some adhesive action, added to an adhesive to reduce the amount of primary binder required per unit area. See also *binder*, *diluent*, *filler*, and *thinner*.

Extensibility

The ability of a material to extend or elongate upon application of sufficient force, expressed as a percent of the original length.

Extensional-Bending Composite

A property of certain classes of laminates that exhibit bending curvatures when subjected to extensional loading.

Extensometer

An instrument for measuring changes in length over a given gauge length caused by application or removal of a force. Commonly used in tension testing.

External Circuit

The wires, connectors, measuring devices, current sources, etc., that are used to bring about or measure the desired electrical conditions within the test cell. It is this portion of the cell through which electrons travel.

E

Externally Pressurized Seal

A seal that operates on a thin film at the interface with the mating surface. The film is formed by high-pressure fluid that is brought to the interface at some mid-dam location and that is at a pressure equal to, or higher than, the upstream seal pressure. See also *hydrostatic seal*.

Extinction

A decrease in the intensity of the diffracted x-ray beam caused by perfection or near perfection of crystal structure. See also *primary extinction* and *secondary extinction*.

Extra Hard

A *temper* of nonferrous alloys and some ferrous alloys characterized by values of tensile strength and hardness about one-third of the way from those of *full hard* to those of *extra spring temper*.

Extra Spring

A *temper* of nonferrous alloys and some ferrous alloys corresponding approximately to a cold worked state above *full hard* beyond which further cold work will not measurably increase strength or hardness.

Extraction

A general term denoting chemical methods of isolating phases from a metal matrix.

Extractive Metallurgy

The branch of *process metallurgy* dealing with the winning of metals from their ores. Compare with *refining*.

Extreme-Pressure Lubricant

A lubricant that imparts increased load-carrying capacity to rubbing surfaces under severe operating conditions. Extreme-pressure lubricants usually contain sulfur, halogens, or phosphorus. The term *antiscuffing lubricant* has been suggested as a replacement for extreme-pressure lubricant.

Extreme-Pressure Lubrication

A condition of lubrication in which the friction and wear between two surfaces in relative motion depend upon the reaction of the lubricant with a rubbing surface at elevated temperature.

Extruded Hole

A hole formed by a punch that first cleanly cuts a hole and then is pushed farther through to form a flange with an enlargement of the original hole.

Extruded Metals

Extrusion is the forcing of solid metal through a suitably shaped orifice under compressive forces. Extrusion is somewhat analogous to squeezing toothpaste through a tube, although some cold extrusion processes more nearly resemble forging, which also deforms metals by application of compressive forces. Most metals can be extruded, although the process may not be economically feasible for high-strength alloys.

Hot Extrusion

The most widely used method for producing extruded shapes is a direct, hot extrusion process. In this process, a heated billet of metal is placed in a cylindrical chamber and then compressed by a hydraulically operated ram. The opposite end of the cylinder contains a die having an orifice of the desired shape; as this die opening is the path of least resistance for the billet under pressure, the metal "squirts" out of the opening as a continuous bar with the same cross-sectional shape as the opening. By using two sets of dies, stepped extrusions can be made. The small section is extruded to the desired length, the small split die is replaced by the large die, and the large section is then extruded.

The most outstanding feature of the extrusion process is its ability to produce a wide variety of section configurations. Structural shapes can be extruded that have complex nonuniform and nonsymmetrical sections that would be difficult or impossible to roll.

In many instances, extrusions can replace bulky assemblies made up by joining, welding, or riveting rolled structural shapes, or sections previously machined from bar, plate, or pipe.

An extrusion die is relatively simple to make and inexpensive when compared to a pair of rolls or a set of forging dies. The low cost of dies and the short lead time for die changes make it possible to extrude small quantities more economically than by most other methods.

Lubricants are used to minimize friction and protect the die surfaces. Graphite is a common lubricant for nonferrous alloys, whereas for hot extrusion of steel, glass is an excellent lubricant.

Indirect, or inverted, extrusion was developed to overcome such difficulties as surface friction and entrainment of surface oxide of direct extrusion. In the indirect process the ram is hollow, the die opening is in the dummy block, and the opposite end of the cylinder is closed. As the ram advances, the billet does not move as in the case of direct extrusion, and the metal is extruded backward through the die and the hollow ram. However, the process is not very popular because the hollow ram is weaker, resulting in lower machine capacity; trouble-free operation requires that the extruded product be straight and not hit the inside of the ram.

Cold Extrusion

The extrusion of cold metal is variously termed *cold pressing*, *cold forging*, *cold extrusion forging*, *extrusion pressing*, and *impact extrusion*. The term *cold extrusion* has become popular in the steel fabrication industry, while *impact extrusion* is more widely used in the nonferrous field.

The original process (identified as *impact extrusion*) consists of the punch (generally moving at high velocity) striking a blank (or slug) of the metal to be extruded, which has been placed in a cavity of a die. Clearance is left between the punch in the die walls; as the punch comes in contact with the blank, the metal has nowhere to go except through the annular opening between punch and die. The punch moves a distance that is controlled by a press setting. This distance determines the base thickness of the finished part. The process is particularly adaptable to the production of thin-walled, tubular-shaped parts with thick bottoms, such as toothpaste tubes.

Advantages of cold extrusion are high strength because of severe strain-hardening, good finish and dimensional accuracy, and economy due to fewer operations and minimum machining required.

Metals Extruded

Extrusion can be used to fabricate practically all structural metals and alloys. Among the more common metals extruded on a

commercial or semi-commercial basis are alloys in the following metal systems:

Magnesium	Carbon and alloy steels
Aluminum	Stainless steel
Brass	Iron superalloys
Copper	Nickel superalloys
Titanium	Columbium or Niobium
Zirconium	Molybdenum
Beryllium	Tantalum
Nickel	Tungsten

These materials span a range of working temperatures from about 316°C to 2205°C, in approximately the order shown above.

The wide range of extrusion temperatures gives rise to the major differences in processing that center around such variables as extrusion lubricants, die materials, die design, billet preparation, and extrusion speed. Present tool materials are capable of maintaining adequate strength and wear resistance for extrusion at temperatures only slightly higher than 538°C. At higher temperatures, lubricants are necessary not only to reduce friction but to insulate and protect the tooling surface from overheating. Also, the speed of extrusion must be more rapid to avoid prolonged contact between the tools and the hot billet. Thus, the extrusion method for magnesium and aluminum is quite different from that for the other metal systems.

The Light Alloys

Magnesium and aluminum are extruded at temperatures below 538°C with no lubrication and flat, sharp-cornered dies. Deformation of the billet occurs by shear flow, which is from within the billet so that the surface skin of the billet is retained in the container as discard. This type of turbulent flow is possible because of the ability of these materials to form sound welds when severely deformed, but requires comparatively slow pressing speeds, often less than 1.66 m/min. With clean tools and no lubricants there are no contaminants present to cause internal defects or laminations, and several sections can be extruded at one time by using multihole dies. Precise dimensional control is attained with ordinary hot-work tool-steel dies, which last for hundreds of extrusions.

Other Metals

With higher-temperature materials, for example, titanium, steels, refractory metals, it is necessary to use lubricants and die designs so that deformation occurs by uniform flow. In this case, the surface of the billet becomes the surface of the extrusion; otherwise, laminations and inclusions could occur. Graphitic lubricants are suitable for producing relatively short lengths at temperatures up to about 1093°C if the operation is performed at high speeds. The Ugine-Sejournet process in which molten glass serves as a lubricant is most widely used for high-temperature extrusion. Because of the insulating as well as lubricating properties of glass, overheating of tools does not occur and die life is increased. For titanium and steels, dies are usually made of tungsten hot-work tool steels. Ceramic coatings (Al_2O_3 or ZrO_2) on the dies are necessary at the temperatures required for refractory metals. Pressing speeds are usually in the range of 8.33–33.32 m/min.

Shape, Surface, and Tolerance Limitations

Extruded shapes are generally classified by configuration and include rod, bar, tube, and hollow, semihollow, and solid shape.

Although many asymmetrical shapes can be produced, probably the most important factor in the extrudability is symmetry. Hollow and semihollow shapes cost more than solid shapes and usually cannot be extruded with as thin sections. Semihollow shapes with long thin voids should be avoided. For best extrudability the length-to-width ratio of partially enclosed voids, channels, or grooves should not exceed 3:1 for aluminum and magnesium, 2:1 for brass, or 1:1 for copper, titanium, and steels. Wall thickness surrounding the voids should be as uniform as possible.

The size and weight of extruded shapes are limited both by the section configuration and by the material properties. The maximum size that can be extruded on a press of given capacity is determined by the circumscribing circle, which is the smallest circle that will enclose the shape. The circumscribing circle size controls the die size, which in turn is limited by the press size.

Thickness limitations are related to the size of the cross section as well as the type of material. As a rule, thicker sections are required with increased section size.

Sharp corners and edges are usually possible with aluminum and magnesium alloys, but 0.38 mm corner and fillet radii are preferred. Minimum fillet radii of 3.2 mm for steel and 4.5 mm for titanium are suggested by most extruders. Typical minimum corner radii are 0.8 mm for steel and 1.5 mm for titanium.

Smooth surfaces with finishes better than 30 μm rms are readily attainable in aluminum and magnesium alloys. High-temperature alloys are characteristically rougher; and extruded finish of 125 μm rms is generally considered acceptable for most steels and titanium alloys. Improved surface finishes can be produced by a cold-draw finishing operation.

Although extruded shapes minimize and often eliminate the need for machining, they do not possess the dimensional accuracy of machined parts. The tolerances of any given dimension vary somewhat depending on the size and type of shape, and the relative location of the dimension. Detailed standard tolerances covering straightness, flatness, twist, and cross-sectional dimensions such as section thickness, angles, contours, and corner and fillet radii have been established for magnesium, aluminum, copper, and brass by most extruders and are published in handbooks. Standard tolerances also have been established for steels and titanium alloys in simple sections, but in many instances these are subject to mill inquiry.

Extrudable Materials

Extrusion is a process for making articles of constant cross-section, called "continuous shapes," by forcing softened material through a hole approximating the desired shape. With plastics, the process is carried out by one of two methods: ram extrusion or screw extrusion.

In ram extrusion, the softened mass fills a cylinder to which the die—the shaped hole—is attached at one end. A closely fitting piston, the ram, enters the cylinder and pushes the mass through the die at pressures ranging up to 68 MPa. The product, or extrudate, is cooled or otherwise hardened shortly after leaving the die. Subsequent handling depends on the material and the shape. Ram extrusion is used chiefly for extruding TFE fluorocarbon (*tetrafluoroethylene*) resin (*Teflon*), which is damaged by the shearing action of screw extrusion, and for *cellulose nitrate*, whose extreme heat sensitivity and inflammability make screw extrusion dangerous.

Screw extrusion, by far the more economical and commercially important process, centers around the screw extruder. This consists of a heavy cylindrical barrel inside which turns a motor-driven screw, or worm. The screw is essentially a thick shaft with a helical blade, or flight, wrapped around it. At the rear end of the barrel, a feed hopper admits cold plastic particles that normally fall into the screw channel

E

by gravity. As the screw rotates, the particles are dragged forward by frictional action between screw, plastic, and barrel. Electric band heaters on the outside of the barrel heat the plastic, which is further heated by the frictional action of the screw. Soon, the particles coalesce into a voidless mass that softens further to become a melt. This plastic melt is very viscous (a million times as viscous as water), so considerable pressure, on the order of 3.4–68 MPa, must be developed to force it through the die at the front of the extruder at economical rates.

Excludable Materials

All thermoplastics can be extruded by either ram or screw extrusion. Today, high-viscosity grades of type 66 nylon and other nylons are available and their extrusion presents no special difficulties. In extruding rigid polyvinyl chloride (PVC), extreme care must be taken not to overheat the resin since thermal decomposition, once started, snowballs. This simply means being careful to avoid extreme temperatures everywhere and to streamline meticulously all passages through which the melt must pass. To a lesser degree, CFE fluorocarbon (*trifluorochloroethylene*) resin (Kel-F et al.), cellulotics, nylons, and acetal (*polyoxymethylene*) are similarly heat-sensitive.

Kel-F® is a registered trade name of 3M Company. In 1996, 3M discontinued manufacturing of Kel-F and today, PCTFE resin is manufactured by Daikin under the trade name of Neoflon® or by Allied Signal under the trade name of Acion®. PolyChloroTriFluoroEthylene is a fluorocarbon-based polymer and is commonly abbreviated PCTFE. PCTFE (polychlorotrifluoroethylene), sometimes has been referred to as Kel-F®. PCTFE (polychlorotrifluoroethylene) is offered as sheet, rod, and tube.

Some thermosets can be extruded provided they are formulated to flow at temperature safely below the curing temperatures. The process has been used to make pipe and structural shapes, to coat wire with thermosetting compositions, and to prepare “rope” and pellets for compression molding. The extrusion of rubbers closely resembles plastics extrusion.

Extruder (Plastics)

A machine that accepts solid particles, such as pellets or powder, or liquid (molten) feed, conveys it through a surrounding barrel by means of a rotating screw, and pumps it, under pressure, through an orifice.

Extrusion (Ceramics)

(1) The process of forcing a mixture of plastic binder and ceramic powder through the opening (s) of a die at relatively high pressure. The material may thus be compacted and emerges in elongated cylindrical or ribbon (or wire, etc.) form having the cross-section of the die opening. Ordinarily followed by drying, curing, activating, or firing. (2) The process of forming clay products by forcing the plastic material through a die.

Extrusion Billet

A metal slug used as *extrusion stock*.

Extrusion Blow Molding

The most common blow molding process, in which a parison is extruded from a plastic melt and is then entrapped between the halves of a mold. The parison is expanded, under air pressure, against the mold cavity to form the part, and is then cooled, removed, and trimmed. See the term *blow molding*.

Extrusion Coating

Using a resin to coat a substrate by extruding a thin film of molten resin and pressing it onto or into the substrate, or both, without the use of an adhesive.

Extrusion Defect

Defects appearing in the last portion of an extrusion to emerge from the die. It is a characteristic of direct extrusion caused when the contamination on the exterior of the billet is effectively held back by friction against the cylinder wall and is then swept across the face of the ram to emerge initially at the center of the extrusion section. As extrusion continues, the defect forms an annulus progressively moving toward the exterior surface. Normally, the last 10%–20% is discarded because of this phenomenon. It is also termed *back end defect*. See preferred term *extrusion pipe*.

Extrusion Forging

(1) Forcing metal into or through a die opening by restricting flow in other directions. (2) A part made by the operation.

Extrusion Ingot

A cast metal slug uses *extrusion stock*.

Extrusion Pipe

A central oxide-lined discontinuity that occasionally occurs in the last 10%–20% of an extruded metal bar. It is caused by the oxidized outer surface of the billet flowing around the end of the billet and into the center of the bar during the final stages of extrusion. Also called *coring*.

Extrusion Stock

A rod, bar, or other section used to make extrusions.

Exudation

The action by which all or a portion of the low melting constituent of a powder metallurgy compact is forced to the surface during sintering; sometimes referred to as bleed out or sweating.

Eyeleted Hole

In an engineering context, this usually refers to a hole with a raised integral rim. Apart from any decorative aspect the rim, correctly formed, can reduce chaffing on material passing through or by the hole, improve the stiffness of sheet and reduce fatigue susceptibility. More generally, the term may refer to a hole which is protected by an added eyelet as in the eyelet applied to the lace holes of shoes.

Eyeletting

The displacing of material about an opening in sheet or plate so that a lip protruding above the surface is formed.

Eyepiece

A lens or system of lenses for increasing magnification in a microscope by magnifying the image formed by the objective.

Fabric Fill Face

That side of a woven fabric used in reinforced plastics on which the greatest number of yarns are perpendicular to the *selvage*.

Fabric Prepreg Batch

In composites processing, a prepreg containing fabric from one fabric batch and impregnated with one batch of resin and one continuous operation.

Fabric Warp Face

That side of a woven fabric used in reinforced plastics on which the greatest number of yarns are parallel to the *selvage*.

Fabrication Traces

Anomalous markings that may appear on crack surfaces of ceramics where the developing crack encounters regions of unusual weakness, density, or elastic modulus, introduced, usually inadvertently, during fabrication.

Fabrics, Nonwoven Bonded

Although there are several types of fabrics that are not woven, the term *nonwoven fabrics* is recognized in the textile trade as applying to those materials composed of a fibrous web held together with a bonding agent to obtain fabric-like qualities. These fabrics may be of a uniform, close-bonded fibrous structure or of a foraminous unitary construction.

They may be formed by processing on modifications either of textile type machines or papermaking equipment. In either case, the fibers as laid up in the basic web prior to bonding or to postforming may be oriented in one or more prescribed directions, or maybe distributed in a completely random fashion. They are secured in place by suitable adhesives incorporated in the web. The application of these adhesives may be controlled to coat and bond the fibers completely, or to bond them only in selected areas, or at points of individual fiber contact.

Nonwovens may be thick or thin and of either low or high density. The conditions under which nonwoven fabrics are manufactured and the possible combinations of fibers and adhesives permit the production of structures offering a wide range of physical and chemical properties.

Production Methods

Production of a nonwoven fabric may be divided into two basic steps: (1) formation of the web and (2) bonding the web. The most widely used means for forming the web is a series of cotton cards feeding to a common conveyor belt to build up a unidirectional composite web of the desired weight. The number of cards per line will depend on the maximum weight of the product to be produced. Each card in the

line may be geared to produce webs ranging from some 35 grains up to 100 grains/yard at speeds of 66.66 m/min down to 15 m/min for the heavier material. Material from these lines is usually limited to 101.6 cm widths, with strength favoring the machine direction over the cross machine direction in ratios from 3:1 to as much as 20:1. Where wider material of heavier weight, or when the strength balanced in the machine and cross machine directions is required, a web production line consisting of a single breaker and a finisher garnet equipped with a cross lapper may be used to advantage.

The most versatile type of web for nonwoven fabrics is that produced by the air disposition of precarded fibers that are collected with a minimum of orientation as a uniform mat.

In contrast to nonwoven fabrics made from webs that have been dry-processed on modified textile equipment are those produced from wet-layup webs using papermaking machines. Such webs usually depend on adhesive additives or postbonding to impart the necessary physical properties.

Once the web has been formed by either the dry or wet-layup process, it may be further modified by techniques such as needle punching, aeration, or impingement with gaseous, liquid, or other means, to produce a patterned configuration of desired characteristics.

Nonwovens of such postformed webs may be characterized by added resistance to delamination, superior drape, flexibility, porosity, abrasion, and flame resistance or other desirable properties.

Types of Fibers

In the production of nonwoven fabrics, every type of natural and anthropogenic fiber can be used. Price, equipment, and quality, as well as chemical and physical requirements of the product, govern the particular fiber used as well as the bonding agent. The use of more virgin first-quality fiber, especially the anthropogenic celluloses, is preferred, in everything from diapers to casket liners.

Rayon is the predominant fiber used for both utility as well as esthetic appeal. It is made in a wide variety of descriptions to fit the different manufacturing methods and end-use requirements. The finer deniers give the best tensile, tear, and bursting strength values. For special applications calling for particular chemical or electrical resistance, more use of the expensive synthetic fibers such as **Acrlan**, nylon, or **Dacron** may be warranted.

Bonding Agents

Properties of nonwoven fabrics are as dependent on the bonding agent as they are on the fiber that forms the foundation of the material. Both are selected with the end use in mind, and each must be compatible with the other.

Bonding agents may be grouped into three broad classifications: (1) liquid dispersions, (2) powdered adhesives, and (3) thermoplastic fibers.

Liquid Dispersions

Liquid dispersions are the most extensive type used. Among these are polyvinyl alcohol, generally used as a preliminary binder or

F

where high strength and permanence are not essential; polyvinyl acetate for good strength and flexibility where freedom from odor and taste are important; polyvinyl chloride (PVC) for good wet and dry strength, and toughness; synthetic lattices of butadiene–acrylonitrile or butadiene–styrene for good adhesive and elastic properties where strength and a high degree of permanence are more important than color, stability, and odor; the acrylics for good strength, soft “hand,” color stability, and permanence. These dispersions are applied (1) by spraying, generally used for low-density materials, (2) by saturator, for denser, more durable material, and (3) by printing, usually for selective bonding of localized areas in soft absorbent products.

Powdered Adhesives

These are usually of thermosetting or thermoplastic resin types and are sifted into the fiber web as formed. They are used especially in the low-density, high-bulk nonwovens where wetting by the binder or the application of pressure might cause excessive matting and compression of the material. Bonding is effected by heating either with or without the use of pressure.

Thermoplastic Fibers

The thermoplastic fiber binders have the advantage of constituting an integrated structural part of the fiber web that forms the fabric. To bond the web, they may be activated by solvents or by heat and pressure. By regulation of the amount of heat and pressure as well as the amount of thermoplastic fiber present, a wide variety of characteristics may be built into these nonwoven fabrics.

Applications

Construction and performance of nonwoven fabrics have not been standardized. They are usually constructed to fit a particular end-use requirement or are built around particular specifications.

Industrial products for which nonwoven fabrics have been used include acoustical curtains; artificial leather and chamois; automotive plumpers; backing for adhesive tapes; base for vinyl and rubber coatings; bagging; buffing wheels; cable and wire wrappings; electrical tapes; filters for air, gases, and liquids; insulation; laminate reinforcements; polishing and wiping cloths; and wall coverings.

Fabrics, Woven

By far the greatest volume of textile materials is used in consumer textiles, such as apparel. But textiles are extremely versatile materials, which have been applied to a large number of engineered uses, for example, thermal, acoustical, and electrical insulation; padding and packaging; barrier applications; filtration, both dry and wet; upholstery and seating; reinforcing for plastics or rubber; and various mechanical uses such as fire hose jackets, tenting, tarpaulins, parachutes, and marine lines.

Textiles are highly complex materials. Their properties depend not only on the fiber but also on the form in which it is used—whether the form be a felt, a bonded fabric, a woven or knit fabric, or cordage. Properties such as heat, chemical, and weather resistance depend primarily on the type of fiber used; properties such as mechanical strength, thermal transmission, and air or liquid permeability depend both on the fiber and the textile form.

The versatility of textiles stems from (1) the wide range of fibers that can be used, and (2) the range of complicated textile structures that can be formed from the fibers.

There are two important factors that should be considered in discussing textile needs with textile suppliers:

1. The types of finishes that can be applied to the finished textile product can substantially alter or modify the stability, “hand,” and/or durability of the textile.
2. Combining of textiles with other materials, such as resins or rubber, either by impregnation or by coating, will substantially alter performance characteristics of the final composite.

Textile Constructions

Textile engineering materials can be classified generally as (1) nonwoven fabrics, including both felts and bonded fabrics; (2) woven or knit fabrics; and (3) cordage.

Woven and Knit Fabrics

Woven fabrics and knit fabrics are composed of webs of fiber yarns. The yarns may be of either filament (continuous) or staple (short) fibers. In knit fabrics, the yarns are fastened to each other by interlocking loops to form the web. In woven fabrics, the yarns are interlaced at right angles to each other to produce the web. The lengthwise yarns are called the warp, and the crosswise ones are the filling (or woof) yarns.

The many variations of woven fabrics can be grouped into four basic weaves. In the plain weave fabric, each filling yarn alternates up and under successive warp yarns. With a plain weave, the most yarn interlacings per square inch can be obtained for maximum density, “cover,” and impermeability. The tightness or openness of the weave, of course, can be varied to any desired degree. In twill weave fabrics, a sharp diagonal line is produced by the warp yarn crossing over two or more filling yarns. Satin weave fabrics are characterized by regularly spaced interlacings at wide intervals. This weave produces a porous fabric with a smooth surface. Satins woven of cotton are called sateen. In the leno weave fabrics, the warp yarns are twisted and the filling yarns are threaded through the twist openings. This weave is used for meshed fabrics and nets.

Cordage

The term *cordage* includes all types of threads, twine, rope, and hawser. Essentially all cordage consists of fibers twisted together, plied, and in many cases cabled to produce essentially continuous strands of desired cross section and strength.

In addition to the type of fiber used, the most important determinants of the end properties of cordage are the type and degree of twist employed. The two major types of twist are (1) cable twist, in which the direction of twisting is alternated in each successive operation, that is, singles may be “S” twisted, plies “Z” twisted, and cables “S” twisted (a yarn or cord has an “S” twist if, when held in a vertical position, the spirals conform in direction of slope to the central portion of the letter “S,” and a “Z” twist if the spirals conform in direction of slope to the central portion of the letter “Z”), and (2) hawser twist, in which the singles, plies, and cables are twisted “SSZ” or “ZZS.” Hawser twist generally provides higher strength and resilience.

Applications

Astroquartz II and *III* fabrics are made of 95% fused-silica fiber filament yarns, featuring light weight, high strength, low dielectrics, and thermal and chemical stability.

While the largest single use of woven fabrics is, of course, for wearing apparel, they are used in many areas; in mechanical applications such as machine and conveyor belting, for filtration, for packaging, and as reinforcement for plastics and rubber.

Specifications

Textile specifications contain two important types of information: (1) descriptive information and (2) service property requirements.

Specifications that physically describe the textile fabric usually include (1) width, in inches, (2) weight, usually in ounces per square yard, (3) type of weave, such as twill, broken twill, leno, or satin, (4) thread count, both in warp and filling (e.g., 68 × 44 denotes 68 warp yarns/in. and 44 filling yarns/in.), (5) type of fiber and whether the yarn is to be filament or staple, (6) crimp, in percent, (7) twist per inch, and (8) yarn number both for warp and fill.

Yarn number designations are somewhat complex as they have been developed in a relatively unorganized fashion over the years, and different systems are used in different types of fibers. (Filament yarns are usually stated simply in denier, which is the weight in grams of 9000 m of yarn.)

Essentially, yarn numbers provide a measure of weight per unit length or length per unit weight. A typical yarn designation on a specification may appear as “210 (denier)/1 × 20/2 (cotton system).” This means that (1) the warp yarn is 210-denier single yarn, and (2) the filling yarn contains 2 plies, each of which is a 20 singles yarn (determined by the cotton numbering system).

A number of fabric-designation systems have been formalized by tradition. For example, sheetings, drills, twills, jeans, broken twills, and sateens are designated only by width in inches, number of linear yards per pound, and number of warp and filling threads per inch. “Specs” for equivalent synthetic fabrics also include fiber type, whether staple or filament.

Face (Crystal)

An idiomorphic plane surface on a crystal.

Face (Machine Tools)

In a lathe tool, the surface against which the chips bear as they are formed. See the term *single-point tool*.

Face Feed

The application of filler metal to the joint, usually by hand, during brazing and soldering.

Face Mill

See *axial rake angle*, *axial relief angle*, *radial rake angle*, *radial relief angle* and *corner* and *end cutting edge angle*, and *single relief angle*.

Face Milling

Milling a surface that is perpendicular to the cutter axis. See also *milling*.

Face of Weld

The exposed surface of an arc or gas weld on the side from which the welding was done. See also the term *fillet weld*.

Face Pressure

In seals, the face load divided by the contacting area of the sealing lip. The face load is the sum of the pneumatic or hydraulic force and the spring force. For lip seals and packings, the face load also includes the interference load. See also *face seal*.

Face Reinforcement

Reinforcement of a weld at the side of the joint from which welding was carried out. See also *root reinforcement*.

Face Seal

A device that prevents the leakage of fluids along rotating shafts, sealing is accomplished by a stationary primary-seal ring bearing against the face of a mating ring mounted on a shaft. Axial pressure maintains the contact between seal ring and mating ring.

Face Shield (Welding)

A device positioned in front of the eyes and a portion of, or all of, the face, whose predominant function is protection of the eyes and face during welding, brazing, or soldering.

Face-Centered

Having atoms or groups of atoms separated by translations of $\frac{1}{2}$, $\frac{1}{2}$, 0; $\frac{1}{2}$, 0, $\frac{1}{2}$; and 0, $\frac{1}{2}$, $\frac{1}{2}$ from a similar atom or group of atoms. The number of atoms in a face-centered cell must be a multiple of 4. See also the term *unit cell*.

Face-Centered Cubic

A crystal lattice in which atoms are close packed, that is, in contact with six others in the same layer and with three others on the layers above and below, and in which the layer alignment repeats every third layer. Close packed hexagonal is similar except that the layer alignment repeats on alternate layers.

Facet

A flat, usually brightly reflective, portion of surface on a crystal or fracture face.

Face-Type Cutters

Cutters that can be mounted directly on and driven from the machine spindle nose.

Facing

(1) In machining, generating a surface on a rotating workpiece by the traverse of a tool perpendicular to the axis of rotation. (2) In foundry practice, any material applied in a wet or dry condition to the face of a mold or core to improve the surface of the casting. See also *mold wash*. (3) For abrasion resistance, see preferred term *hardfacing*.

F

Factor of Safety

See *safety factor*.

Fadeometer

An apparatus for determining the resistance of resins and other materials to fading.

Fagot

In forging work, a bundle of iron bars or rods that will be heated and then hammered and welded to form a single bar. The term may imply some careful, tidy arrangement. Fagot (ed) iron was the result of rolling or forging carefully packed bundles of wrought iron.

Fail Safe

The concept whereby it is recognized that if a failure occurs it will do so in a manner that does not involve hazard to, for example, humans or the environment, although there could be acceptable economic cost. In some contexts, the term implies that the mode of failure is acceptable, as in the case of the braking system on some vehicles in which the brakes are applied if the brake system fails; in other cases, it implies that in the event of a failure some secondary systems will intervene or provide support before a hazard develops. See also *leak-before-break*.

Failure

A general term used to imply that a part in service (a) has become completely inoperable, (b) is still operable but incapable of satisfactorily performing its intended function, or (c) has deteriorated seriously, to the point that it has become unreliable or unsafe for continued use.

Failure Criteria

The limiting conditions relating to the admissibility of the deviation from the characteristic value due to changes after the beginning of stress.

Failure Mechanism

A structural or chemical process, such as corrosion or fatigue, that causes failure.

Fairing

A secondary structure in airframes and ship hulls, the major function of which is to streamline the airflow or flow of fluid by producing a smooth outline and reducing drag.

Falling Weight Test

A crude form of impact testing in which a weight is allowed to fall onto the center of a bar or rail, etc., supported at its ends.

False Bottom

An *insert* put in either member of a die set to increase the strength and improve the life of the die.

False Brinelling

(1) Damage to a solid bearing surface characterized by indentations not caused by plastic deformation resulting from overload, but thought to be due to other causes such as *fretting corrosion*. (2) Local spots appearing when the protective film on a metal is broken continually by repeated impacts, usually in the presence of corrosive agents. The appearance is generally similar to that produced by *Brinelling* but corrosion products are usually visible. It may result from fretting corrosion. This term should be avoided when a more precise description is possible. False Brinelling (race fretting) can be distinguished from true *Brinelling* because in false Brinelling, surface material is removed so that original finishing marks are removed. The borders of a false Brinell mark are sharply defined, whereas a dent caused by a rolling element does not have sharp edges and the finishing marks are visible in the bottom of the dent. Contrast with *Brinelling*.

False Indication

In nondestructive inspection, an *indication* that may be interpreted erroneously as an *imperfection*. See also *artifact*.

False Wiring

Same as *curling*.

Family Mold

A multicavity mold used for forming of plastic in which each of the cavities form one of the component parts of the assembled finished object. The term is often applied to a mold in which parts from different customers are grouped together for economy. Sometimes called combination mold.

Farad (F)

A unit of electric capacity.

Faraday's Law

(1) The amount of any substance dissolved or deposited in electrolysis is proportional to the total electric charge passed. (2) The amounts of different substances dissolved or deposited by the passage of the same electric charge are proportional to their equivalent weights.

Far-Infrared Radiation

Infrared radiation in the wavelength range of 30–300 μm (3×10^5 to 3×10^6 Å).

Fast Fracture

Fracture occurring virtually instantaneously as opposed to mechanisms such as fatigue and creep which develop over a period of time. The term is also often used loosely as a synonym for brittle, as opposed to fast neutrons—neutrons with energies greater than 0.1 MeV.

Fasteners

Mechanical fasteners are among the most common components in fabricated products. Thus, fasteners are extremely important from

both a manufacturing and a product standpoint. The proper selection of fasteners is necessary to provide the most value for the manufacturer as well as for the consumer.

The most common types of fasteners can be grouped into the following categories: bolts/screws, studs, pins, nuts, rivets, and holes with or without threads tapped into them.

Fastener Types and Materials Selection

Bolts and screws, two names for externally threaded fasteners, are certainly well-recognized fastener types. Like all fasteners, they are also a highly engineered method of joining. The significant features of a bolt are the tensile force on the bolt and the compressive loading of the joint members when applied.

The ability of a bolt to translate rotational motion into a clamping force has made it the standard fastener. The common bolt is also an ideal fastener from a reusability standpoint. Its helical thread form enables it to attach, detach, then reattach joint members an almost infinite number of times. The simple tools required are another reason that bolts have become so common. Bolts provide an excellent ratio of performance to cost, but during the design phase and installation, they require more consideration than other fastener types to achieve an optimized joint.

Many different materials types are available for fasteners. Standard metric bolts and nuts are made of steels with varying chemical compositions.

A rivet is a nonreusable fastener that is deformed to provide a mechanical clenching of joint members. Both aluminum and steel may be fabricated into rivets. In fact, the stem and body of a rivet can be easily made with two different materials. Low-carbon steel alloys in the AISI/SAE 1XXX series may be selected when cost is the most important factor, or when a higher-strength rivet is needed. Typical tensile strength values for joints made with steel rivets are 5–10 kN, which is about one-third to half the value of equivalently sized bolts. An aluminum rivet usually has about half to two-thirds the strength of steel rivets.

However, the shear resistance of both types of rivets can equal their tensile resistance, and can even exceed the value for a similar sized bolt. The typical aluminum alloys for rivets in automotive applications are AA 5052, 5056, 7075, 7178, and 2014. These alloys provide good strength, high corrosion resistance (without the need for additional corrosion protection), and light weight.

Some rivets are made of thermoplastics, namely, polyamide 6 (PA6), polyamide 66 (PA66), and polyoxymethylene (POM). These are semicrystalline polymers with high strength, low mass, and resistance to automotive fluids and salt environments. As a result, they are also ideal for the myriad pins and clips that connect plastic components.

Polyamides are also coated onto bolts and nuts and the plastic is added to reduce the allowance between the mating metallic threads, making them more resistant to vibrational loosening.

Fluoropolymers are commonly added to the threaded region of weld nuts prior to installation because of their low coefficient of friction.

Finally, polymer adhesives are often added to bolts. These bolts resist vibrational loosening through mechanical means, such as thermoplastic additions or locally deformed features. In fact, the application of adhesives is the only method that provides long-term resistance to loosening.

A final material being considered for fasteners is titanium. The mechanical properties of titanium are rather high. If low density is also required, as it is for automotive structures, then titanium appears to be the only current material that can challenge traditional

steel alloys. The workhorse alloy titanium, 6% aluminum, 4% vanadium (Ti-6Al-4V) could definitely be chosen for fastener applications.

The advantages of titanium are its extremely high strength-to-weight ratio and its almost complete imperviousness to corrosive attack by chloride ions. This means that a lower-mass fastener can be made, one that does not require the expensive and time-consuming application of corrosion-resistant coatings. Many mechanical joints in aerospace structures currently rely on titanium alloys, including Ti-6Al-4V.

If the raw material costs of titanium can be reduced, it will become a viable alternative material for automotive applications, with fasteners at the top of the list.

Fatigue

The development of one or more cracks by the repeated application and removal of a stress significantly less than the tensile strength of the material. Components are normally expected to fail at a stress equivalent to their ultimate tensile strength, see tensile *test*. However, if a component is subjected to repeated cycles of application and removal of a lower stress it may ultimately fail by fatigue. Damage occurs by the initiation, usually at the surface, of a fatigue crack which, over time, propagates until the remaining intact section is insufficient to carry the load. The damage is often highly localized at major features such as manufacturing or welding defects or section changes. “Fatigue” or colloquially “metal fatigue” does not mean that the bulk material away from the crack has deteriorated in any general sense. Many millions of cycles of loading, perhaps over years, may be required to cause failure and, generalizing, in the absence of large initiating defects a considerable proportion of the total component life is occupied in developing a crack to a detectable size. Once initiated, cracks usually propagate at an increasing rate. The number of cycles to failure, in specified circumstances of loading, is termed the fatigue life and, as might be expected, the higher the stress the less the number of cycles required to cause failure. Consequently, failure occurring within a few thousand cycles is conventionally termed either low cycle fatigue or high strain fatigue. If more than about 10,000 cycles are required the mechanism can be termed either high cycle fatigue or low strain fatigue. The fatigue properties of the material are commonly determined by testing a series of test pieces over ranges of stress (more accurately stress amplitude as defined below). The results, in terms of the number of cycles to failure at each stress amplitude, are then plotted on an S/N curve. For most steels there is a level of stress amplitude below which a component will survive an infinite number of cycles. This stress is usually termed the fatigue limit. The ratio of fatigue limit to the tensile strength is termed the fatigue ratio and is typically about 50% for steels up to about 1100 MPa (75 tons/in.²) U.T.S. For many other metals, a fatigue limit cannot be defined as failure will eventually occur if sufficient cycles are experienced. In these cases, it is normal to determine an endurance (or endurance limit). This is the maximum stress amplitude that can be tolerated to survive some specified number of cycles, often 10 million and hence endurance Ratio is the ratio of endurance to the U.T.S. The term endurance may also be used of steels, possibly as an alternative to fatigue limit but particularly where the stresses exceed the fatigue limit. Up to this point, it has been assumed that the fatigue cycle is very simple, merely the application and removal of a load. However, the cycle is often more complex than this. There is always a cyclic stress but it may range from tensile to compressive and there may also be an additional constant stress. In these complex circumstances the various stresses are normally resolved

F

into the mean stress and the stress amplitude or stress range (nearly double the stress amplitude). Here are some examples. The hanging and other crane cable experiences a repeated stress or pulsating stress ranging from the point when unloaded (ignoring the hook) to high tensile when loaded—an example of high amplitude, moderate mean stress loading. A lift (elevator) cable experiences a fluctuating stress comprising a constant stress due to the cabin plus an additional stress due to passengers—an example of high mean stress and medium amplitude loading. A clock hair spring is deflected backwards and forwards either side of its unstressed rest position so a point on its periphery experience and Alternating stress or reversed stress ranging from highly tensile to highly compressive—an example of high amplitude, zero mean stress loading. The combined effect of the mean stress and the cyclic stress can be determined from various empirical relationships established, with varying degrees of conservatism. Reference may also be made to the stress ratio “R,” which is the ratio of minimum stress to maximum stress or to stress, ratio “A,” which is the ratio of alternating stress amplitude to mean stress.

Fatigue Crack Growth Rate (da/dN)

The rate of crack extension caused by constant-amplitude fatigue loading, expressed in terms of crack extension per cycle of load application, and plotted logarithmically against the stress intensity factor range, ΔK .

Fatigue Ductility (D_f)

The ability of a material to deform plastically before fracturing, determined from a constant-strain amplitude, low-cycle fatigue test. Usually expressed in percent in direct analogy with elongation and reduction in area ductility measures.

Fatigue Ductility Exponent (c)

The slope of a log-log plot of the plastic strain range and the fatigue life.

Fatigue Failure

Failure that occurs when a specimen undergoing *fatigue* completely fractures into two parts or has softened or been otherwise significantly reduced in stiffness by thermal heating or cracking.

Fatigue Life (N)

(1) The number of cycles of stress or strain of a specified character that a given specimen sustains before failure of a specified nature occurs. (2) The number of cycles of deformation required to bring about failure of a test specimen under a given set of oscillating conditions (stresses or strains). See also *S-N curve*.

Fatigue Life for $p\%$ Survival

An estimate of the fatigue life that $p\%$ of the population would attain or exceed at a given stress level. The observed value of the median fatigue life estimates the fatigue life for 50% survival. Fatigue life for $p\%$ survival values, where p is any number, such as 95, 90, etc., may also be estimated from the individual fatigue life values.

Fatigue Limit

The maximum stress that presumably leads to fatigue fracture in a specified number of stress cycles. The value of the *maximum stress* and the *stress ratio* also should be stated. See also *endurance limit*.

Fatigue Limit for $p\%$ Survival

The limiting value of fatigue strength for $p\%$ survival as N becomes very large; p may be any number, such as 95, 90, etc.

Fatigue Notch Factor (K_f)

The ratio of the *fatigue strength* of a unnotched specimen to a fatigue strength of a notched specimen of the same material and condition; both strengths are determined at the same number of *stress cycles*.

Fatigue Notch Sensitivity (q)

An estimate of the effect of a notch or hole of a given size and shape on the fatigue properties of a material, measured by $q = (K_f - 1)/(K_t - 1)$, where K_f is the *fatigue notch factor* and K_t is the *stress-concentration factor*. A material is said to be fully notch sensitive if q approaches a value of 1.0; it is not notch sensitive if the ratio approaches 0.

Fatigue Ratio

The ratio of fatigue strength to tensile strength. Mean stress and alternating stress must be stated.

Fatigue Strength

The maximum cyclical stress a material can withstand for a given number of cycles before failure occurs.

Fatigue Strength at N Cycles (S_N)

A hypothetical value of stress for failure at exactly N cycles as determined from an *S-N* diagram. The value of S_N that is commonly found in the literature is the hypothetical value of maximum stress, $S_{\max}$, minimum stress $S_{\min}$ or stress amplitude, S_a at which 50% of the specimens of a given sample could survive N stress cycles in which the mean stress $S_m = 0$. This is also known as the *median fatigue strength at N cycles*. See also *S-N curve*.

Fatigue Strength for $p\%$ Survival at N Cycles

An estimate of the stress level at which $p\%$ of the population would survive N cycles; p may be any number, such as 95, 90, etc. The estimates of the fatigue strength for $p\%$ survival values are derived from particular points of the fatigue life distribution since there is no test procedure by which a frequency distribution of fatigue strength at N cycles can be directly observed.

Fatigue Striation (Metals)

Parallel lines frequently observed in electron microscope fractographs or fatigue fracture surfaces. The lines are transverse to the direction of local crack propagation; the distance between successive lines represents the advance of the crack front during the one cycle of stress variation.

Fatigue Test

A method for determining the range of alternating (fluctuating) stresses a material can withstand without failing.

Fatigue Wear

(1) Removal of particles detached by fatigue arising from cyclic stress variations. (2) Wear of a solid surface caused by fracture arising from material fatigue. See also *spalling*.

Fatigue-Strength Reduction Factor

The ratio of the fatigue strength of a member or specimen with no stress concentration to the fatigue strength with stress concentration. This factor has no meaning unless the stress range and the shape, size, and material of the member or specimen are stated.

Fats

Natural combinations of glycerin with fatty acids, so-called *triglycerides*, some fats having as many as 10 or more different fatty acids in the combination. At ambient temperature fats are solids; if liquid, they are normally called *fat oils*. Fats are also known as *lipids*. *Waxes* differ slightly in composition from fats and are mixed esters of polyhydric alcohols, other than glycerin, and fatty acids. *Animal fats* are *butter*, *lard*, and edible and inedible *tallows*. Fats contain less than 5% of phospholipids, pigments, vitamins, anti-oxidants, and sterols. They are derived from animal or vegetable sources, the latter source being chiefly the seeds or nuts of plants. Fats in a pure state would be odorless, tasteless, and colorless, but the natural fats always contain other substances that give characteristic odors and tastes. Fats are used directly in foods and in the making of various foodstuffs. They are used in making soaps, candles, and lubricants, and in the compounding of resins and coatings. They are also distilled or chemically split to obtain the fatty acids. Crude fats are refined to remove nonglyceride impurities, including free fatty acids, phosphatides, and proteinaceous and mucilaginous matter, by treatment with strong caustic soda. The fatty acids are converted to oil-insoluble soaps known as foos or soap stock.

Fats are most important for food, containing more than twice the fuel value of other foods. They are also important carriers of glycerin necessary to the human system. Metabolism, or absorption of fats into the system, is not a simple process and is varied with the presence of other food materials. The fats with melting points above 45°C are not readily absorbed into the system. The heavy fats are called tallow. Lack of certain fats or fatty acids causes skin diseases, scaly skin, and other conditions. Some fatty acids are poisonous alone, but in the glyceride form in the fats they may not be poisonous but beneficial. Fats can be made synthetically from petroleum or coal. The world resources of natural fats are potentially unlimited, especially from tropical knots, forming a cheap source of fatty acids in readily available form.

Margarine, *shortening*, *confectionery fat*, and other edible fats are made by hydrogenating a variety of semisolid or liquid fats. The hardening process converts unsaturated fatty glycerides to more saturated forms. About one cubic meter of hydrogen is needed per metric ton of oil to reduce the oils iodine number one unit. The catalyst is nickel.

Engineered, invitation, or *artificial fats* represent a new market for products that have low-calorie saturated fat, or cholesterol contents. They are predominately mixtures of such hydrogenated vegetable oils as soybean, corn, peanut, palm, and cottonseed.

Fatty Acids

A series of *organic acids* deriving the name from the fact that the higher members of the series, the most common ones, occur naturally in animal fats, but fatty acids are readily synthesized, and the possible variety is almost infinite. All these acids contain the *carboxyl group* •COOH. The acids are used for making soaps, candles, and coating compounds; as plasticizers; and for the production of plastics and many chemicals. The hydrogen atom of the group can be replaced by metals or alkyl radicals with the formation of salts or esters, and other derivatives such as the halides, anhydrides, peroxides, and amides can also be made. Some of the fatty acids can be polymerized to form plastics. Various derivatives of the acids are used as flavors, perfumes, driers, pharmaceuticals, and antiseptics. Certain fatty acids, such as oleic and stearic, are common to most fats and oils regardless of their source, while others, such as arachidic and ericic, are characteristic only of specific fats and oils.

Saturated acids are acids that contain all the hydrogen with which they can combine. They have high melting points. *Unsaturated acids*, such as oleic, linoleic, are liquid at room temperature and are less stable than saturated acids. Fatty acid glycerides in the form of animal and vegetable fats form an essential group of human foods. Fats of the highly unsaturated acids are necessary in the metabolism of the human body, the glycerides of the saturated acids such as palmitic being insufficient alone for food.

Polyunsaturated acids of the linoleic type with more than one double bond lower blood cholesterol, but saturated acids with no double bond do not. *Arachidonic acid* with four double bonds lowers blood cholesterol greatly. It is manufactured in the body from linoleic acid if vitamin B₆ is present. *Linoleic acid*, the characteristic unsaturated food acid, has two double bonds. *Linoleic acid*, found in linseed oil, has three double bonds.

The names of the fatty acids often suggest their natural sources, though commercially they may be derived from other sources or made synthetically. *Butyric acid* is the characteristic acid of butter. Also called *butanoic acid* and *ethylacetic acid*, it is made synthetically as a colorless liquid with a strong odor and completely soluble in water. With alcohols its forms butyrates of pleasant fruity odors used as flavors.

Faying Surface

The surfaces of materials in contact with each other and joined or about to be joined.

F.C.C.

See *face-centered cubic*.

Feasibility

The ability of a grease to flow to the suction of a pump.

Feather (Ceramics)

A striation having the appearance of a feather. See also *striation*.

Feathering

The tapering of an *adherend* on one side to form a wedge section, as used in an adhesively bonded scarf joint.

F

Feed

(1) The material entering a process or its rate of introduction. (2) The rate at which material is cut. Depending on context, it may refer to the depth of cut or the rate at which a tool traverses a surface or a combination of the two.

Feed Hopper

A container used for holding metal powder prior to compacting in a press.

Feed Lines

Lynn earmarks on a machine or ground surface that are spaced at intervals equal to the *feed* per revolution or per stroke.

Feed Rate (Thermal Spraying)

The rate at which material passes through the gun in a unit of time. A synonym for *spray rate*.

Feeder (Feeder Head, Feed Head)

A channel through which molten metal is fed to a casting. A reservoir of material that remains molten to feed shrinkage in the solidifying casting below. In foundry practice, a *riser*.

Feeding

(1) In casting, providing molten metal to a region undergoing solidification, usually at a rate sufficient to fill the mold cavity ahead of the solidification front and to compensate for any shrinkage accompanied solidification. (2) Conveying metal stock or workpieces to a location for use or processing, such as wire to a consumable electrode, strip to a die, or workpieces to an assembler.

Feeler Gauge

A strip of metal of high precision thickness to measure or set gaps.

Feldspar

A group of alumina silicate minerals consisting chiefly of microcline ($K_2O \cdot Al_2O_3 \cdot 6SiO_2$), albite ($Na_2O \cdot Al_2O_3 \cdot 6SiO_2$), and/or anorthite ($CaO \cdot Al_2O_3 \cdot 2SiO_2$) used in the production of glass and ceramic whiteware. Feldspar constitutes 60% of the outer 13–17 km of the earth's crust and is the most common mineral in crystalline rocks. Feldspars are aluminum silicates of barium, calcium, sodium, and potassium.

The importance of the many feldspars that occur so widely in igneous, metamorphic, and some sedimentary rocks cannot be underestimated, especially from the viewpoint of a petrologist attempting to unravel Earth history.

With weathering, feldspars form commercially important clay materials. Economically, feldspars are valued as raw material for the ceramic and glass industries, as fluxes in iron smelting, and as constituents of scouring powders. Occasionally, their luster or colors qualify them as semiprecious gemstones. Some decorative building and monument stones are predominantly composed of weather-resistant feldspars.

Knowledge of the composition of a feldspar and its crystal structure is indispensable to an understanding of its properties. However, it is the distribution of the aluminum and silicon atoms among the available tetrahedral sites in each chemical species that is essential to a complete classification scheme, and is of great importance in unraveling clues to the crystallization and thermal history of many igneous and metamorphic rocks.

Felt Metal

A substantial felt fabric reinforced with fine metal strands. The strands may be loosely woven or bonded for improved strength. The term may be extended to similar materials where the reinforcement is plastic.

Felts

Classes of felts in use as engineering materials are wool and synthetic fiber felts.

Wool felt is a fabric obtained as a result of the interlocking of wool fibers under suitable combinations of mechanical work, chemical action, moisture, and heat, alone or in combination with other fibers.

Synthetic fiber felt is a fabric obtained as a result of interlocking of synthetic fibers by mechanical action. Other fibers include asbestos, cotton, glass, and so forth. See also *batt*.

Properties

Neither wool nor synthetic fiber felts require binders and exist as 100% fibrous materials.

Felts generally exhibit the same chemical properties as do the fibers of which the felt is composed. Wool felts are characterized by excellent resistance to acids but are damaged by exposure to strong alkalis. They exhibit remarkable resistance to atmospheric aging and are as a class probably the most inert of all nonmetallic engineering materials with respect to nonaqueous liquids, oils, or solvents. Wool felts are not generally recommended for stressed dry uses at temperatures in excess of 82°C, because of changes in physical properties, but are used as dry spacers and gaskets in many applications up to 149°C, and the use of the materials as oil wicks and lubricating system components at ambient temperatures up to 149°C is common.

Synthetic fiber felts are available in virtually all classes of fiber composition including regenerated cellulose, cellulose acetate, cellulose triacetate, polyamide, polyester, acrylic, modacrylic, olefin, and CFC fluorocarbon (tetrafluoroethylene). The variety of types available provides a virtually infinite range of physical and chemical properties for application beyond the natural versatility of wool fiber felts. Outstanding among the properties of this class of engineering material are chemical, solvent, thermal, and biological stability as well as low moisture absorption, quick drying after aqueous wetting, abrasion resistance, and frictional and dielectrical features.

Forms

Wool felts are produced as "sheet" stock in a standard 91.4 × 91.4 cm size in thickness ranging from 1.6 to 76 mm. There are a number of density classifications based on the weight for a 914 × 914 mm sheet in 25.4 mm thickness from 5.4 to 14.4 kg with the weight for any given thickness in the density class proportioned to the weight per square meter at the 25.4 mm thickness. "Roll" felts are produced in

either 1522 or 1830 mm widths in lengths up to 160 m and standard thicknesses range from 0.8 to 25.4 mm.

Synthetic fiber felt widths are available from 600 to 1830 mm in thicknesses from 0.8 to 19 mm.

Both wool and synthetic fiber felts are nonforming and nonraveling and thus provide considerable ease of cutting and fabricating. In addition, wool felt lends itself to most grinding, cutting, shaping, extruding, and other machining operations so that special shaped parts such as polishing laps, round wicking, ink rollers, and others are produced.

Applications

The structural elasticity of felts as a class makes these materials suitable for molding and forming and parts of these types are produced to provide special shaped gaskets, seals, fillers, instrument covers, and the like. In many cases, these shaped parts are stabilized through the use of resinous or rubber impregnants and this modified class of felt is finding ever-increasing use as flat stock for special gasketing, sealing, and other applications. Combinations of felt and plastic and elastomer sheet materials are also produced for application where resilience plus nonpermeability is desired as in sealing and frictional uses.

Use of felt as an engineering material covers a broad spectrum of application. Major contributing properties include resilience, mechanical, thermal, and acoustic energy absorption; high porosity-to-weight ratio; resistance to aging; thermal and chemical stability; high effective surface area per unit volume; and solvent resistance.

Applied uses include wet and dry filtration, thermal and acoustical insulation, vibration isolation, impact absorption, cushioning and packaging, polishing, frictional surfacing, liquid absorption and reservoirs, wicking, gasketing, sealing, and percussion mechanical dampening.

FEP

See *fluorinated ethylene propylene*.

Ferric Oxide

The red *iron oxide*, Fe_2O_3 , also called gamma ferric oxide, found in abundance as the ore *hematite*, or made by calcining the sulfate. It has a dark-red color and comes in powder or lumps. It is used as a paint pigment under such names as *Indian red*, *Persian red*, and *Persian gulf oxide*. In cosmetics and in polishing compounds it is called *rouge*.

The names *metallic red* and *metallic brown* are applied to pigments from Pennsylvania ores containing a high percentage of *red iron oxide*. *Venetian red* is a name for red iron oxide pigments mixed with various fillers, most commonly an equal proportion of the pigment extender calcium sulfate. Commercially, it is made by heating ferrous sulfate with quicklime in a furnace. Venetian red is a permanent and inert pigment that is generally used on wood. It cannot be used on many metals, including iron, because the calcium sulfate can cause corrosion. The *Tuscan red* treatments are red iron oxide blended with up to 75% of lakes, but may also be barium sulfate with lakes. *Ferric oxide pigments* make low-priced paints and are much used as base coats for structural steel work.

Yellow iron oxide, known as *ferrite yellow* and *Mars yellow*, is used as a paint pigment. It is made by precipitating ferrous hydroxide from iron sulfate and lime and then oxidizing to the yellow oxide. *Black ferric oxide* is a reddish-black amorphous powder and is used as a paint pigment for polishing compounds and for decarburizing steel.

Ferrimagnetic Material

(1) A material that macroscopically has properties similar to those of a *ferromagnetic material* but that microscopically also resembles an antiferromagnetic material in that some of the elementary magnetic moments are aligned antiparallel. If the moments are of different magnitudes, the material may still have a large resultant magnetization. (2) A material in which unequal magnetic moments are lined up antiparallel to each other. Permeabilities are of the same order of magnitude as those of ferromagnetic materials, but are lower than they would be if all atomic moments were parallel and in the same direction. Under ordinary conditions, the magnetic characteristics of ferrimagnetic materials are quite similar to those of ferromagnetic material.

Ferrite

(1) A solid solution of one or more elements in body-centered cubic iron. Unless otherwise designated (for instance, as chromium ferrite), the solute is generally assumed to be carbon. On some equilibrium diagrams, there are two ferrite regions separated by an austenite area. The lower area is alpha ferrite; the upper, delta ferrite. If there is no designation, alpha ferrite is assumed. (2) An essentially carbon-free solid solution in which alpha iron is the solvent, and which is characterized by a body-centered cubic crystal structure. Fully ferritic steels are only obtained when the carbon content is quite low. The most obvious microstructural features of such metals are the ferrite grain boundaries.

Ferrite

A ferrite is any of the class of magnetic oxides. Typically, the ferrites have a crystal structure that has more than one type of site for the cations. Usually, the magnetic moments of the metal ions on sites of one type are parallel to each other, and antiparallel to the moments on at least one site of another type. Thus, ferrites exhibit ferromagnetism.

A term referring to magnetic oxides in general, and especially to material having the formula MOFe_2O_3 , where M is a divalent metal ion or a combination of such ions. Certain ferrites, magnetically "soft," are useful for core applications at radio and higher frequencies because of their advantageous magnetic properties and high volume resistivity. Other ferrites, magnetically "hard" in character, have desirable permanent magnet properties.

Commercial Types

There are three important classes of commercial ferrites. One class has the spinel structure. The second class of commercially important ferrites has the garnet structure. Yttrium-based garnets are used in microwave devices. Thin monocrystalline films of complex garnets have been developed for bubble domain memory devices. The third class of ferrites has a hexagonal structure of the magneto-plumbite type. Because of their large magneto crystalline anisotropy, the hexagonal ferrites develop high coercivity and are an important member of the permanent magnet family.

Properties

The important intrinsic parameters of a ferrite are the saturation magnetization, Curie temperature, and magnetocrystalline (K_1) and magnetostrictive (Ω_s) anisotropies. These properties are determined by the choice of the cations and their distribution in the various sites.

F

In addition to the intrinsic magnetic parameters, microstructure plays an equally important role in determining device properties. Thus, grain size, porosity, chemical homogeneity, and foreign inclusions dictate in part such technical properties as permeability, line width, remanence, and coercivity in polycrystalline ceramics. In garnet films for bubble domain device applications, the film must essentially be free of all defects such as inclusions, growth pits, and dislocations.

Preparation

Polycrystalline ferrites are most economically prepared by ceramic techniques. Component oxides or carbonates are mixed, calcined at elevated temperatures for partial compound formation, and then granulated by ball milling. Dispersants, plasticizers, and lubricants are added, and the resultant slurry is spray-dried, followed by pressing to desired shape and sintering. The last step completes the chemical reaction to the desired magnetic structure and effects homogenization, densification, and grain growth of the compact. It is perhaps the most critical step in optimizing the magnetic properties of commercial ferrites.

Ferrite Banding

Parallel bands of free ferrite aligned in the direction of working. Sometimes referred to as *ferrite streaks*.

Ferrite Devices

These are electrical devices whose principle of operation is based on the use and properties of ferrites, which are magnetic oxides. Ferrite devices are divided into two categories, depending on whether the ferrite is magnetically soft (low coercivity) or hard (high coercivity). Soft ferrites are used primarily as transformers, inductors, and recording heads, and in microwave devices. Since the electrical resistivity of soft ferrites is typically 10^6 – 10^{11} times that of metals, ferrite components have much lower eddy current losses and hence are used at frequencies generally above about 10 kHz. Hard ferrites are used in permanent-magnet motors, loudspeakers, and holding devices, and as storage media in magnetic recording devices.

Chemistry and Crystal Structure

Soft ferrite devices are spinels with the general formula of MFe_2O_4 , in which M is a divalent metal ion. The commercially practical ferrites are those in which the divalent ion represents one or more magnesium, manganese, iron, cobalt, nickel, copper, zinc, and cadmium ions. The trivalent iron ion may also be substituted by other trivalent ions such as aluminum. The compositions are carefully adjusted to optimize the device requirements, such as permeability, loss, ferromagnetic resonance line width, and so forth.

The ferromagnetic garnets have the general formula of $M_3Fe_5O_{12}$, in which M is a rare earth or yttrium ion. Single-crystal garnet films form the basis of bubble domain device technology. Bulk garnets have applications in microwave devices.

Hard ferrites for permanent-magnetic device applications have the hexagonal magneto-plumbite structure, with the general formula $MFe_{12}O_{19}$, where M is usually barium or strontium.

The material of choice for magnetic recording is δ - Fe_2O_3 , which has a spinel structure.

With the exception of some single crystals used in recording heads and special microwave applications, and particulates used

as storage media in magnetic recording, all ferrites are prepared in polycrystalline form by ceramic techniques.

Applications

Applications of ferrites may be divided into nonmicrowave, microwave, and magnetic recording applications. Further, the nonmicrowave applications may be divided into categories determined by the magnetic properties based on the B - H behavior, that is, the variation of the magnetic induction or flux density B with magnetic field strength H . The categories are linear B - H , with low flux density, and nonlinear B - H , with medium to high flux density. The highly nonlinear B - H , with a square or rectangular hysteresis loop, was once exploited in computer memory cores.

Linear B - H Devices

In the linear region, the most important devices are high-quality inductors, particularly those used in filters in frequency-division multiplex telecommunications systems and low-power wideband and pulse transformers. Virtually all such devices are made of either MnZn ferrite or NiZn ferrite, although predominantly the former.

Nonlinear B - H Devices

The largest usage of ferrite measured in terms of material weight is in the nonlinear B - H range and is found in the form of deflecting yokes and flyback transformers for television receivers. Again, MnZn and NiZn ferrites dominate the use in these devices.

A rapidly growing use of ferrites is in the power area, where ferrite transformers are extensively used in switched mode (AC-DC) and converter mode (DC-DC) power supplies. Such power supplies are widely used in various computer peripheral equipment and private exchange telephone systems.

Microwave Devices

Microwave devices make use of the reciprocal propagation characteristics of ferrites close to or at a gyromagnetic resonance frequency in the range of 1–100 GHz. The most important of such devices are isolators and circulators. The garnets have highly desirable, small, ferromagnetic-resonance line widths, particularly in single-crystal form.

Magnetic Recording Devices

Vast amounts of audio and video information and digital data from computers are stored in magnetic tapes and disks. Here magnetic recording materials function as hard magnetic materials. The most widely used particles in magnetic recording are δ - Fe_2O_3 and co-modified δ - Fe_2O_3 . The basic δ - Fe_2O_3 is generally used in audio recording, while the higher-coercivity Co- δ - Fe_2O_3 dominates video recording.

Ferrite Number

An arbitrary, standardized value designating the ferrite content of an austenitic stainless steel weld metal. This value directly replaces percent ferrite or volume percent ferrite and is determined by the magnetic test described in AWS A4.2.

Ferrite Streaks

Same as *ferrite banding*.

Ferrite–Pearlite Banding

Inhomogeneous distribution of ferrite and pearlite aligned in filaments or plates parallel to the direction of working. See the term *banding*.

Ferritic Grain Size

The grain size of the ferritic matrix of a steel.

Ferritic Malleable

See *malleable cast iron*.

Ferritic Stainless Steel

See *stainless steels*.

Ferritic Steels

Steels in which the predominant phase is ferrite. Such steels range from virtually pure iron to complex high alloys. They are magnetic and, with sufficient carbon, can be hardened by rapid cooling. See *steel*.

Ferritizing Anneal

A treatment given as-cast gray or ductile (nodular) iron to produce an essentially ferritic matrix. For the term to be meaningful, the final microstructure desired or the time–temperature cycle used must be specified.

Ferroalloys

Ferroalloys compose an important group of metallic raw materials required for the steel industry. Ferroalloys are the principal source of such additions as silicon and manganese, which are required for even the simplest plain-carbon steels, and chromium, vanadium, tungsten, titanium, and molybdenum, which are used in both low- and high-alloy steels. Also included are many other more complex alloys. Ferroalloys are unique in that they are brittle and otherwise unsuited for any service application, but they are important as the most economical source of these elements for use in the manufacture of the engineering alloys. These same elements can also be obtained, at much greater cost in most cases, as essentially pure metals. The ferroalloys contain significant amounts of iron and usually have a lower melting range than the pure metals and are therefore dissolved by the molten steel more readily than the pure metal. In other cases, the other elements in though ferroalloy serve to protect the critical element against oxidation during solution and thereby give higher recoveries. Ferroalloys are used both as deoxidizers and as a specified addition to give particular properties to the steel.

Many ferroalloys contain combinations of two or more desirable alloy additions, and well over 100 commercial grades and combinations are available. Although of less general importance, other sources of these elements for steel making are metallic nickel, nickel, SiC, Mo₂O₃, and even misch metal (a mixture of rare earths).

The three ferroalloys that account for the major tonnage in this class are the various grades of silicon, manganese, and chromium. For example, 5.9 kg of manganese is used on the average in the United States for every ton of open-hearth steel produced.

Elements supplied as ferroalloys are among the most difficult metals to reduce from ore.

Ferrochromium

A high-chromium iron master alloy used for adding chromium to irons and steel, ferrochromium is also called ferrochrome. It is made from chromite ore by smelting with lime, silica, or fluorspar in an electric furnace. High-carbon-ferrochrome is used for making tool steels, ball-bearing steels, and other alloy steels. It melts at about 1250°C. Low-carbon-ferrochrome is used for making stainless steels and acid-resistant steels. Simplex ferrochrome comes in pellet form and is used for making low-carbon stainless steels. Low-carbon ferrochrome is also preferred for alloy steel mixtures where much scrap is used because it keeps down the carbon and inhibits the formation of hard chromium carbides. The various grades of ferrochromium are also marketed as high-N₂ ferrochrome, and for use in making high-chromium cast steels where the N₂ refines the grain and increases the strength. Foundry-grade ferrochrome is used for making cast irons, as well as for ladle additions to cast iron to give uniform structure and increase the strength and hardness.

Ferroelectric

A crystalline material that exhibits spontaneous electrical polarization, hysteresis, and piezoelectric properties.

Ferroelectric Effect

The phenomenon whereby certain crystals may exhibit a spontaneous dipole moment (which is called ferroelectric by analogy with ferromagnetism exhibiting a permanent magnetic moment). Ferroelectric crystals often show several Curie points, domain structures, and hysteresis, much as do ferromagnetic crystals.

Ferrograph

An instrument used to determine the size distribution of wear particles in lubricating oils of mechanical systems. The technique relies on the debris being capable of being attracted to a magnet. In addition, it displays on a screen, the magnetic characteristics of a material, particularly hysteresis curves.

Ferromagnetic Material

A material that in general exhibits the phenomena of hysteresis and saturation, and whose permeability is dependent on the magnetizing force. Microscopically, the elementary magnets are aligned parallel in volumes called *domains*. The unmagnetized condition of a ferromagnetic material results from the overall neutralization of the magnetization of the domains to produce zero external magnetization.

Ferromagnetic Resonance

Magnetic resonance of a ferromagnetic material. See also *ferromagnetism* and *magnetic resonance*.

Ferromagnetism

A property exhibited by certain metals, alloys, and compounds of the transition (iron group), rare earth, and actinide elements in

F

which, below a certain temperature termed the Curie temperature, the atomic magnetic moments tend to line up in a common direction. Ferromagnetism is characterized by the strong attraction of one magnetized body for another. See also *Curie temperature*. Compare with *paramagnetism*.

Ferromanganese

This is a master alloy of manganese and iron used for deoxidizing steels, and for adding manganese to iron and steel alloys and bronzes. Manganese is the common deoxidizer and cleanser of steel, forming oxides and sulfides that are carried off in the slag. Ferromanganese is made from the ores in either the blast furnace or the electric furnace. Spiegeleisen is a form of low-manganese ferromanganese and the German name, meaning mirror iron, is derived from the fact that the crystals of the fractured face shine like mirrors. Spiegeleisen has the advantage that it can be made from low-grade manganese ores, but the quantity needed to obtain the required proportion of manganese in the steel is so great that it must be premelted before adding to the steel. It was used for making irons and steels by the Bessemer process.

Ferrophosphorus

This substance is an iron containing a high percentage of phosphorus, used for adding phosphorus to steels. Small amounts of phosphorus are used in open-hearth steels to make them free-cutting, and phosphorus is also employed in tinplate steels to prevent the sheets from sticking together in annealing. Ferrophosphorus is made by melting phosphate rock together with the ore in making pig iron. There is also a master alloy, ferroselenium, for adding selenium to steels, especially stainless steels, to give free-machining qualities.

Ferrosilicon

This is a high-silicon master alloy used for making silicon steels, and for adding silicon to transformer irons and steels. It is made in the electric furnace by fusing quartz or silica with iron turnings and carbon. Silicon is often added to steels in combination alloys with deoxidizers or other alloying elements. Ferrosilicon aluminum is a more effective deoxidizer for steel than aluminum alone. It is also used for adding silicon to aluminum casting alloys. The alloy serves as a deoxidizer, fluxes the slag inclusions, and also controls the grain size of the steel.

Ferrotitanium

A master alloy of titanium with iron, ferrotitanium is used as a purifying agent for irons and steel owing to the great affinity of titanium for O_2 and N_2 at temperatures above $800^\circ C$. The value of the alloy is as a cleanser, and little or no titanium remains in the steel unless the percentage is gauged to leave a residue. The ferrocarbon titanium is made from ilmenite in the electric furnace, and the carbon-free alloy is made by reduction of the ore with aluminum. Ferrotitanium comes in lumps, crushed, or screened, and it is used for ladle additions for cleansing steel. Low-carbon ferrotitanium is used as a deoxidizer and as a carbide stabilizer in high-chromium steels. Graphidox improves the fluidity of steel, increases machinability, and adds a small amount of titanium to increase the yield strength, and the Grainal alloys that are used to control alloy steels and have various compositions.

MnTi is used as a deoxidizer for high-grade steels and for nonferrous alloys.

NiTi is used for hard nonferrous alloys and columbium is used for adding columbium to steel. It has an exothermic reaction that prevents chilling of the molten metal.

Ferrous

Metallic materials in which the principal component is iron.

Ferrous Oxide

Black iron oxide, FeO .

Ferrous P/M

Specifying powder-metallurgy (P/M) parts and their consolidation process used to be a simple process: Design the part, select the metal powders and lubricants that provide the required properties, compact the powders into a briquette, and sinter the briquette into its finished form. Through this procedure, millions of parts have been produced for applications ranging from automobiles to appliances and from business to farm and garden machines.

However, the needs of industries have changed significantly. Removing weight from all products has risen to primary importance. Energy, tooling, and materials costs now figure prominently in parts design, and productivity has emerged as the new watchword.

With these changes have come changes in P/M technology. Through the many manufacturing processes, improvements have been made in the powders themselves—improvements such as lower levels of inclusions and higher compressibility. In addition to conventional iron and steel metals, the list of available powders has been expanded to include new classes of tool steel, as well as materials such as cermets and alloys of titanium, nickel, and aluminum.

Accompanying these developments has been the growth of new consolidation technologies. As a result, design engineers need current information on which P/M technologies are viable, cost-effective, and production-effective, and which have potentially wide application.

Although P/M is used to fabricate parts from just about any metal, the most commonly used metals are the iron-based alloys. Low-density iron P/M parts ($5.6\text{--}6.0\text{ g/cm}^3$), with a typical tensile strength of 108.8 MPa, are usually used in bearing applications. Copper is commonly added to improve both strength and bearing properties. Alloy-steel powders are sometimes hot-forged to high or nearly theoretical density to form parts with improved mechanical properties that, when heat-treated, may have tensile strengths to 1156 MPa. Powder forging (P/F) is now established as a serious contender for parts formerly made as wrought forgings or machined from mill forms.

Iron P/M or sintered Fe–Cu alloy strength can be varied by adjusting density, carbon content (up to 15%), or all three to satisfy specific design requirements. The mechanical properties of ferrous powder parts can be considerably improved by impregnating or infiltrating them with any one of a number of different materials, both metallic and nonmetallic, such as oil, wax, resins, copper, lead, and babbit.

Low-density P/M parts are used in bearing applications because they provide porosity for oil storage. Impregnating sintered-metal bearings with oil usually eliminates the need for relubrication.

For higher-strength needs, alloyed (frequently prealloyed nickel–molybdenum–iron) iron, compacted to a higher density, is used.

When carbon or other alloying elements are mixed with the iron powders and densities exceed 6.2 g/cm^3 , the parts are considered to be steel rather than iron. As carbon content is increased up to 1%, the strength of steel P/M parts increases, just as the strength of wrought steel increases with higher carbon content.

Ferrous-base P/M parts can range in size from about 2.5 mm thick and 3.2 mm in diameter to 50.8 mm thick and over 612 mm in diameter. Because they can be mass-produced at relatively low-cost, iron-base P/M parts find a wide variety of uses in such high-volume products as appliances, business machines, power tools, and automobiles. Typical parts are gears, bearings, rotors, valves, valve plates, cams, levers, ratchets, and sprockets.

Additional applications can be accommodated by sealing the pores in iron P/M parts. The sealing materials used are copper, polyesters, and anaerobics; each requires a different processing system to impregnate the parts. Impregnation of sintered P/M parts is done for any of several reasons:

- To serve in pressure-tight applications
- To improve surface finish (impregnated parts are platable)
- To improve machinability
- To improve corrosion resistance

Although high precision has been achieved in P/M parts for many years, their application was once restricted because of mechanical property limitations. Now, however, the mechanical properties can be 100% increased in steel P/M parts by hot forging in closed dies. Properties of P/M parts forged to 100% theoretical density in production conditions are claimed to be equal, and sometimes superior, to those of wrought steels of similar composition.

Ferrule

A cylindrical reinforcement or sleeve.

Fettling

Various processes for improving or restoring a component or equipment. For example, trimming flash or other excess material from castings or locally repairing components, furnace linings, etc.

Fiber

(1) The variation in mechanical properties, structure, etc., observed when wrought material is tested or examined in different directions relative to the primary direction of working. For example, plate has a greater strength and ductility in the longitudinal direction than in the thickness direction. (2) Filaments. Thus fiber metal comprises metal fibers packed and sintered together possibly with another material filling the interstices.

Fiber (Composites)

A general term used to refer to filamentary materials. Often, fiber is used synonymously with filament. It is a general term for a filament with a finite length that is at least 100 times its diameter, which is typically 0.10–0.13 mm (0.004–0.005 in.). In most cases, it is prepared by drawing from a molten bath, spinning, or depositing on a substrate. Fibers can be continuous or specific short lengths (discontinuous), normally no less than 3.2 mm (1/8 in.).

Fiber (Metals)

(1) The characteristic of wrought metal that indicates *directional properties* and is revealed by etching of a longitudinal section or is manifested by the fibrous or woody appearance of the fracture. It is caused chiefly by extension of the constituents of the metal, both metallic and nonmetallic, in the direction of working. (2) The pattern of preferred orientation of metal crystals after a given deformation process, usually wire drawing. See also *fibering* and *preferred orientation*.

Fiber Bridging (Composites)

Reinforcing fiber material that bridges an inside radius of a protruded product. This condition is caused by shrinkage stresses around such a radius during cure.

Fiber Content

The amount of fiber present in reinforced plastics and composites, usually expressed as a percentage volume fraction or weight fraction.

Fiber Count

The number of fibers per unit width of ply present in a specified section of a reinforced plastic or composite.

Fiber Diameter

The measurement (expressed in micrometers or microinches) of the diameter of individual filaments used in reinforced plastics or composites.

Fiber Direction (Composites)

The orientation or alignment of the longitudinal axis of a fiber with respect to a stated reference axis.

Fiber Exposure (Composites)

A condition in which reinforcing fibers within the base material are exposed in machined, abraded, or chemically attacked areas. See also *weave exposure*.

Fiber Grease

A type of grease having a pronounced fibrous structure.

Fiber Metallurgy

The technology of producing solid bodies from fibers or chopped filaments, with or without a metal matrix. The fibers may consist of such nonmetals as graphite or aluminum oxide, or of such metals as tungsten or boron. See also *metal-matrix composites*.

Fiber Pattern

Visible fibers on the surface of laminates or molding. The thread size and weave of glass cloth.

F

Fiber Show

Strands or bundles of fibers that are not covered by plastic because they are at or above the surface of a reinforced plastic or composite.

Fiber Stress

The stress acting along the main axis of a fiber. The fiber may be an individual filament or it may be a local unit section of a component that is not uniformly stressed.

Fiber Texture (Metals)

A texture characterized by having only one preferred crystallographic direction.

Fiber Wash (Composites)

Splaying out of woven or nonwoven fibers from the general reinforcement direction. Fibers are carried along with bleeding resin during cure.

Fiberboard

Heavy sheet material of fibers matted and pressed or rolled to form a strong board, used for making containers and partitions and for construction purposes. Almost any organic fiber may be used, with or without a binder. The soft boards are made by felting wood pulp, wood chips, or bagasse, usually without a binder. *Masonite* is produced from by-product woodchips reduced to the cellulose fibers by high steam pressure. The long fibers and the lignin adhesive of the wood are retained, and no chemicals are used in pressing the pulp into boards. Masonite quarter board, for paneling, is made in boards 0.25 in. (0.64 cm) thick. *Presdwood* is a grainless grade made by compressing under hydraulic pressure and is dense and strong.

These types belong to the class known as *hardboard*, in the processing of which the carbohydrates and soluble constituents of the original wood are dissolved out and the relative proportion of lignin is increased, resulting in a grainless, hard, stiff, and water-resistant board free from shrinkage. The specific gravity of most hard boards is greater than 1.0, and the modulus of rupture is from 5,000 to 15,000 lb/in.² (34–103 MPa). The lignin acts as a binder for the fibers, but some hard boards are made harder and more resistant by adding a percentage of an insoluble resin. Densified hardboard, made with high pressure, is 85 lb/ft³ (1362 kg/m³) or greater. Hard boards have uniform strength in all directions and have smooth surfaces.

Irradiated wood is natural wood impregnated with resins of low molecular weight and irradiated with gamma rays from cobalt 60 which cross-links the resin molecules and binds them to the fibers of the wood. The resins add strength and hardness without changing the grain structure and color of the wood. Maple, impregnated with 0.5% by weight of methyl methacrylate and irradiated, is three times as hard as the natural wood but can be worked with ordinary tools. *Particleboards*, made with wood particles, have lower density and have greater flexibility but lower strength than hardboard. The process is not limited to the making of boards. Wood particles are also used for low-cost molded parts, with up to 90% wood particles and the balance urea, phenolic, or melamine resin. Birch and maple particles are preferred.

Wood molding powder is made by the same method of treating with fibers with steam pressure and hydrolyzing the hemicellulose,

leaving the lignin free as a binder. Hardboard is used for counter-tops, flooring, furniture, and jigs and templates.

Hardwood is a hardboard made from hardwood waste compressed into sheets under heat and hydraulic pressure. The surface is hard with a high polish.

Fiberglass

An individual filament made by drawing molten glass. A continuous filament is a glass fiber of great or indefinite length. A staple fiber is a glass fiber of relatively short length, generally less than 430 mm (17 in.), the length depending on the forming or spinning process used. The four main glasses used for Fiberglass are high-alkali glass (A-glass), electrical grade glass (E-glass), a modified E-glass that is chemically resistant (ECR-glass), and high-strength glass (S-glass).

Fiberglass Reinforcement

Major material used to reinforce a plastic. Available as mat, roving, fabric, and so forth, it is incorporated into both thermosets and thermoplastics.

Fiberfing

Elongation and alignment of internal boundaries, second phases, and inclusions in particular directions corresponding to the direction of metal flow during deformation processing.

Fiber-Reinforced Composite

A material consisting of two or more discrete physical phases, in which a fibrous phase is dispersed in a continuous matrix phase. The fibrous phase may be macro-, micro-, or submicroscopic, but it must retain its physical identity so that it could conceivably be removed from the matrix intact.

Fiber-Reinforced Glass

Fiber-reinforced glass (FRG) composites are glass or glass ceramic matrices reinforced with long fibers of carbon or SiC. These composites are lighter than steel but just as strong as many steel grades, and can resist higher temperatures. They also have outstanding resistance to impact, thermal shock, and wear, and can be formulated to control thermal and electrical conductivity. With proper tooling, operations such as drilling, grinding, and turning can be completed in half the time required for non-reinforced glass.

Currently, FRG components are primarily used for handling hot glass or molten aluminum during manufacturing operations. FRG is also under test as an engineering material in a variety of markets, including the aerospace, automotive, and semiconductor industries.

Properties

Glass and glass ceramics are versatile materials because of such characteristics as high chemical resistance and special electrical behavior, but fragility under tensile stress has limited their structural applications. However, the addition of continuous fibers of carbon and SiC into glass produces a material that withstands very high mechanical stresses and loads. As a result, it is now possible to manufacture glass matrix composites that are capable of structural roles.

The reinforcement process provides an increase in both admissible maximum stress and ultimate elongation: brittle fracture is

replaced by an almost ductile behavior. These properties, together with others, make FRG composites advantageous as a material in the machine-building industry. For example, low density and high modulus of elasticity allow extremely strong and stiff structures.

Another important characteristic of long-fiber-reinforced glasses is that their mechanical properties are largely independent of the condition at the surface. This means that they can be drilled, even near edges, and joined with other parts by means of screws and bolts.

In addition, FRG composites have very high resistance to temperature changes, low coefficient of thermal expansion, high specific heat capacity, and good chemical resistance.

They also exhibit good tribological and wear properties. However, because of the great variety of tribological and tribo-mechanical processes and applications, each service environment must be evaluated before selecting an FRG composite.

Fiber Effects

Performance of FRG composites under various operating conditions depends primarily on the type of fiber, the amount of fiber, and its orientation within the matrix. It also depends on the operating environment and the duration or cycle of the specific application.

Fiber Types

Carbon fibers are stable up to $>2000^{\circ}\text{C}$ under inert atmospheres, but few applications require such performance. Moreover, at those temperature levels, the matrix itself becomes soft. In air, carbon fibers remain stable to about 450°C . This temperature limit also applies to composites containing carbon fibers, unless the fibers have been completely sealed.

By contrast, SiC fibers are stable in air up to about 1200°C . In this case, the heat resistance of the matrix is the limiting factor. Therefore, SiC FRG products can be considered stable to 500°C if the matrix consists of the alkali-borosilicate-glass, *Duran*.

On the other hand, if an alkali-free aluminosilicate glass is the matrix, the SiC-fiber-containing composite is stable up to 750°C .

When quenched from 350°C to 20°C , most nonreinforced glasses break. However, SiC FRG is capable of withstanding a 60-fold quench (thermal shock) from 550°C to ambient temperatures. Furthermore, the product has exhibited good fracture toughness at temperatures as low as -200°C .

Amount of Fiber

Performance at high temperatures and resistance to thermal shock can be improved by increasing the percentage of fiber within the composite. However, fiber is the chief cost factor in producing FRG. Therefore, performance advantages must continue to outweigh costs as fiber count is increased.

Fiber Orientation

Depending on the arrangement of the fibers, the properties of a FRG composite can be either isotropic or anisotropic. For example, fibers may be arranged so that heat conductivity is low in one direction, but high in the perpendicular direction. Absolute values of heat conductivity range from 1.7 to $\sim 25\text{ W/m K}$ or half the value of steel. As in high-temperature performance, heat conductivity depends on the direction, type, and amount of fiber in the composite.

Relatively high conductivity values result when the composite contains carbon fibers aligned longitudinally in the direction of heat travel; otherwise, the material may work as a heat barrier.

Similarly, the electrical resistance of composites has been measured at room temperature in a composite 40% fiber by volume. In the fiber direction, specific electrical resistance for the SiC product was $10\ \Omega\text{ cm}$, while for the carbon product, it was $0.01\ \Omega\text{ cm}$. Normal to the fibers, the specific electrical resistance may be several orders of magnitude higher.

Potential Applications

FRG components are used as replacements for asbestos and other materials for handling hot glass during glass manufacturing operations. These include pushers, grips, transporters, and takeout pads as well as other parts in contact with hot glowing glass. It is an application characterized by extreme conditions in terms of heat and thermal shock, in which FRG composites have a great advantage over traditional materials.

Within the metals industry, FRG pads act as thermal buffers in the handling of molten aluminum and its alloys. In this application, they form insulation pads between the melt vessel and supporting structural work, thereby minimizing heat conductivity away from the melt.

Other applications being exploited are the replacement for fragile glass substrates that hold silicon wafers during chemical vapor deposition (CVD) coating processes. Required properties include high fracture toughness for higher yields, a low coefficient of thermal expansion, and high stiffness.

Automotive applications include piston inserts, valve-control components, and other parts subjected to thermal and mechanical shock. FRG may also be applied in products for the protection of areas that must be insulated from heat, or where fracture toughness is needed.

The tribological and wear properties of FRG suggest applications as bearings and seals in pump manufacturing, and for off-road industrial vehicle and equipment brakes. Other potential applications include aerospace components with glass ceramic matrices for temperatures above 1000°C ; scanning-mirror substrates for space and missile systems; and protective inserts for parts requiring high impact resistance. As FRG manufacturing technology advances and costs are reduced, the composites would be suitable for the construction of safes and strong rooms, and as armor in vehicles.

FRG components are being produced in several configurations, which include plates, disks, or rings that have a maximum dimension (length, width, or diameter) of 400 mm, and thickness of 50 mm. The minimum thickness of unprocessed forms is 0.5 mm. Semifinished material can be reprocessed into end products with complex geometric forms.

Fiber-Reinforced Plastics

Fiber-reinforced plastics (FRPs) comprise a broad group of composite materials composed of fibers embedded in a plastic resin matrix. In general, they have relatively high strength-to-weight ratios and excellent corrosion resistance compared to metals. They can be formed economically into virtually any shape and size. In size, FRP products range from tiny electronic components to large boat hulls. Between these extremes, there are a wide variety of FRP gears, bearings, housings, and parts used in all product industries.

FRPs are composed of three major components—matrix, fiber, and bonding agent. The plastic resin serves as the matrix in which are embedded the fibers. Adherence between matrix and fibers is achieved by a bonding agent or binder, sometimes called a coupling agent. Most plastics, both thermosets and thermoplastics, can be the matrix material. In addition to these three major components,

F

a wide variety of additives—fillers, catalysts, inhibitors, stabilizers, pigments, and fire retardants—can be used to fit specific application needs.

Fibers

Glass is by far the most-used fiber in FRPs. Glass-fiber-reinforced plastics are often referred to as GFRP or GRP. Asbestos fiber has some use, but is largely limited in applications where maximum thermal insulation or fire resistance is required. Other fibrous materials used as reinforcements are paper, sisal, cotton, nylon, and Kevlar. For high-performance parts and components, more costly fibers, such as boron, carbon, and graphite, can be specified.

The standard glass fiber used in GRP is a borosilicate type, known as E-glass (E-GI). The fibers are spun as single glass filaments with diameters ranging from 0.01 to 0.03 mm. These filaments, collected into strands, usually around 200 per strand, are manufactured into many forms of reinforcement. The E-GI fibers have a tensile strength of 3447 MPa. Another glass fiber, known as S-GI, is higher in strength, but because of its higher cost its use is limited to advanced, high-performance applications. In general, in reinforced thermoplastics, glass content runs between 20% and 40%; with thermosets it runs as high as 80% in the case of filament-wound structures.

There are a number of standard forms in which glass fiber is produced and applied in GRP.

1. Continuous strands of glass supplied either as twisted, single-end strands (yarn) or as untwisted multistrands (continuous) roving
2. Fabrics woven from yarns in a variety of type, weights, and widths
3. Woven rovings—continuous rovings worked into a coarse, heavy, drapable fabric
4. Chopped strands made from either continuous or spun roving cut into 3.2–12.7 mm lengths
5. Reinforcing mats made of either chopped at random or continuous strand laid down in a random pattern
6. Surfacing mats composed of continuous glass filaments in random patterns

Resins

Although a number of different plastic resins are used as the matrix for reinforced plastics, thermosetting polyester resins are the most common. The combination of polyester and glass provides a good balance of mechanical properties as well as corrosion resistance, low cost, and good dimensional stability. In addition, curing can be done at room temperature without pressure, thus making for low processing equipment costs.

Polyesters are also available as casting resins, both in water-extended formulations for low-cost castings, and in compounds filled with ground wood or pecan-shell flour for furniture components.

Low-profile molding resins are mixtures of polyester resins, thermoplastic polymers, and glass-fiber reinforcements. These are used to mold parts with smooth surfaces that can be painted without the need for prior sanding.

For high-volume production, special sheet-molding compounds (SMC) are available in continuous-sheet form. Resin mixtures of thermoplastics with polyesters have been developed to produce high-quality surfaces in the finished molding.

These polyester resins are available for use as coatings for curing by ultraviolet radiation. These 100%-solids materials cure in a

matter of seconds and release no solvents. Although some styrene may be lost upon exposure to ultraviolet radiation, the amount is small.

Prepregs are partially cured thermoset resin-coated reinforcing fabrics in roll or sheet. The prepregs (short for preimpregnated) can be laid or wrapped in place and then fully cured by heat.

Other glass-reinforced thermosets include phenolics and epoxies. GR (glass-reinforced) phenolics are noted for their low cost and good overall performance in low-strength applications. Because of their good electrical resistivity and low water absorption, they are widely used for electrical housings, circuit boards, and gears. Since epoxies are more expensive than polyesters and phenolics, GR epoxies are limited to high-performance parts where their excellent strength, thermal stability, chemical resistance, and dielectric strength are required.

Initially, GRP materials were largely limited to thermosetting plastics. Today, however more than 1000 different types and grades of reinforced thermoplastics or GR+ P are commercially available. Leaders in volume are nylon and the styrenes. Unlike thermosetting resins, GR+ P parts can be made in standard injection-molding machines. The resin can be supplied as pellets containing chopped glass fibers. As a general rule, a GR+ P with chopped fibers at least doubles the tensile strength and stiffness of the plastic. Glass-reinforced thermoplastics are also produced as the materials for forming on metal-stamping equipment and compression-molding machines.

Processing Methods

Matched Metal Die Molding

This is the most efficient and economical method for mass-producing high-strength parts. Parts are press-molded in matched male and female molds at pressures of 1380–2068 MPa and at heats of 113°C–127°C.

Four main forms of thermosetting resin reinforcement are used:

1. Chopped fiber preforms, shaped like the part, are saturated with resin at the mold. They are best for deep draw, compound curvature parts.
2. Flat mat, saturated with resin at the mold, is used for shallow parts with simple curvature.
3. SMC, a preimpregnated material, has advantages for parts with varying thickness. SMCs consist of polyester resin, long glass fibers (to 5.08 cm), a catalyst, and other additives. They are supplied in rolls, sandwiched between polyethylene carrier films. Uniformity of SMC materials is closely controlled, making these materials especially suited for automated production. Structural SMCs contain up to 65% glass in continuous, as well as random, fiber orientation. This compares with 20%–35% glass, in random orientation only, of conventional SMC.
4. Bulk molding compound (BMC), a premix of polyester resin, short glass fibers (3.2–6.4 mm long), filler, catalyst, and other additives for specific properties. BMC is supplied in bulk form or as extruded rope for ease of handling and it is used for parts similar to castings.

Injection Molding

In this high-volume process, a mix of short fibers and resin is forced by a screw or plunger through an orifice into the heated cavity of a closed matched metal mold. It is the major method for forming reinforced thermoplastics and is used for thermoplastic-modified thermosetting BMCs.

Hand Layup

This is the simplest of all methods of forming thermosetting composites. It is best employed for quantities under 1000, for prototypes and sample runs, for extremely large parts, and for larger volume where model changes are frequent, as in boats. In hand layup, only one mold is used, usually female, which can be made of low-cost wood or plaster. Duplicate molds are inexpensive. The reinforcing mat or fabric is cut to fit, laid in the mold, and saturated with resin by hand, using a brush, roller, or spray gun. Layers are built up to the required thickness; then the laminate is cured to permanent hardness, generally at room temperature.

Spray-Up

Like hand layup, the spray-up method uses a single mold, but it can introduce a degree of automation. This method is good for complex thermoset moldings, and its portable equipment eases on-site fabrication and repair. Short lengths of reinforcement and resin are projected by a specially designed spray gun so they are deposited simultaneously on the surface of the mold. Cure is usually accomplished by a catalyst in the resin at room temperature.

Filament Winding

This method produces moldings with the highest strength-to-weight ratio of any reinforced thermoset because of its high glass-to-resin ratio. It is generally limited to surfaces of revolution—round, oval, tapered, or rectangular—but it can achieve a high degree of automation. Continuous fiber strands are wound on a suitably shaped mandrel or core and precisely positioned in predetermined patterns. The mandrel may be left in place permanently or removed after cure. The strands may be preimpregnated or the resin may be applied during or after winding. Heat is used to effect final cure.

Centrifugal Casting

This is another method of producing round, oval, tapered, or rectangular parts. It offers low labor and tooling costs, uniform wall thicknesses, and good inner and outer surfaces. Chopped fibers and resin are placed inside a mandrel and uniformly distributed as the mandrel is rotated inside an oven.

Continuous Laminating

Continuous laminating is the most economical method of producing flat and corrugated panels, glazing, and similar products in large volume. Reinforcing mat or fabric is impregnated with resin, run-through laminating rolls between cellophane sheets to control thickness and resin content, and then cured in a heating zone.

Pultrusion

Pultrusion produces shapes with high unidirectional strength such as “I” beams, flat stock for building siding, fishing rods, and shafts for golf clubs. Continuous fiber strands, combined with mat or woven fibers for cross strength, are impregnated with resin and pulled through a long heated steel die. The die shapes the product and controls resin content.

Properties

The mechanical properties of fiber composites are dependent on a number of complex factors. Two of the dominating ones in GRPs are the length of fibers and the glass content by weight. In general, strength increases with fiber length. For example, reinforcing a thermoplastic with chopped glass fibers at least doubles the strength of the plastic, whereas long-glass fiber reinforced the plastics

thermoplastics exhibit increases of 300% and 400%. Also heat distortion temperatures usually increase by about 37.8°C, and impact strengths are appreciably increased. Similarly, as a general rule, an increase in glass content results in the following property changes:

- Tensile and impact strength increase.
- Modulus of elasticity increases.
- Heat deflection temperature increases, sometimes as much as 149°C.
- Creep decreases and dimensional stability increases.
- Thermal expansion decreases.

Properties of thermoset polyesters are so dependent on type, compounding, and processing method that a complete listing covering all combinations would be almost impossible. However, typical strength ranges obtainable in parts fabricated from various forms of polyester/glass compounds and processed by several methods can be found in *Encyclopedia of Materials, Parts, and Finishes*, Second Edition, p. 240, CRC Press, 2002.

Fibers

By definition, a fiber has a length at least 100 times its diameter or width, and its length must be at least 0.5 cm. Length also determines whether a fiber is classified as staple or filament. Filaments are long and/or continuous fibers. Staple fibers are relatively short, and, in practical applications, range from under 2.5 to 15.2 cm long (except for rope, where the fibers can run to several centimeters). Of the natural fibers, only silk exists in filament form; synthetics are produced as both staple and filaments.

The internal, microscopic structure of fibers is basically no different from that of other polymeric materials. Each fiber is composed of an aggregate of thousands of polymer molecules. However, in contrast to bulk plastic forms, the polymers in fibers are generally longer and aligned linearly, more or less parallel to the fiber axis. Thus, fibers are generally more crystalline than are bulk forms.

Also in contrast to bulk forms, fibers are not used alone, but either in assemblies or aggregates such as yarn or textiles or as a constituent with other materials, such as in composites. Also, compared with other materials, the properties and behavior of both fibers and textile forms are more critically dependent on their geometry. Hence, fibers are sometimes characterized as tiny microscopic beams, and, as such, their structural properties are dependent on such factors as cross-sectional area and shape, and length. The cross-sectional shape and diameter of fibers vary widely. Glass, nylon, *Dynel*, and *Dacron*, for example, are essentially circular. Some other synthetics are oval, and others are irregular and serrated round. Cotton fibers are round tubes, and silk is triangular.

Fiber diameters range from about 0.01 to 0.04 mm. Because of the irregular cross-section of many fibers, it is common practice to specify diameter or cross-sectional area in terms of fineness, which is defined as a weight-to-length or linear density relationship. One exception is wool, which is graded in micrometers. The common measure of linear density is the denier, which is the weight in grams of a 9000 m length of fiber. Another measure is the tex, which is defined as grams per 1 km. A millitex is the number of grams per 1000 km.

Of course, the linear density, or denier, is also directly related to fiber density. This is expressed as the denier/density value, commonly referred to as denier per unit density, which represents the equivalent denier for a fiber with the same cross-sectional area and a density of 1.

F

The cross-sectional diameter or area generally has a major influence on fiber and textile properties. It affects, for example, yarn packing, weave tightness, fabric stiffness, fabric thickness and weight, and cost relationships. Similarly, the cross-sectional shape affects yarn packing, stiffness, and twisting characteristics. It also affects the surface area, which in turn determines the fiber contact area, air permeability, and other properties.

For efficient production, a number of filaments are pulled simultaneously from several orifices in the bushing. These filaments (usually numbering about 204) are collected into a bundle, called a “strand,” at a gathering device, where a “size” is applied to the filament surfaces. The strand is then wound into a forming package called a “cake.” From this cake, shippable forms of fibrous glass are produced.

Fibers Fracture

A gray and amorphous *fracture* that results when a metal is sufficiently ductile for the crystals to elongate before fracture occurs. When a fibrous fracture is obtained in an impact test, it may be regarded as definite evidence of toughness of the metal. Silky, dull gray and ductile as opposed to bright and crystalline. See also *crystalline fracture* and *silky fracture*.

Fibrillation

Production of fiber from film.

Fibrous Glass

The primary engineering benefits of glass fibers are their (1) inorganic nature, which makes them highly inert; (2) high strength-to-weight ratio; (3) nonflammability; and (4) resistance to heat, fungi, and rotting.

Glass fibers are produced in both filament and staple form. Their major engineering uses are (1) thermal and/or acoustical insulation and (2) as reinforcements, primarily for plastics.

Types

The largest volume of glass fibers used for engineering applications are so-called “E,” made from a lime- Al_2O_3 borosilicate glass that is relatively soda-free. Although its initial strength at the bushing may be about 2758–3447 MPa, surface damage to fibers (both mechanical damage in handling and effects of moisture) reduces usable strengths to 1034–1380 MPa. But at least 1,380 MPa tensile strength, the relatively low density of glass (0.092 lb/ft³) produces a strength-to-weight ratio of about 5, 511, 800 cm, superior to that of a 3,060 MPa tensile strength steel. Modulus of E-glass fibers is about 68,666 MPa. Although essentially unaffected by low temperatures, E-glass is limited to a maximum continuous operating temperature of about 316°C.

Other specialized types of glass (primarily used in specialty reinforced plastics applications) include:

1. *High silica, leached glass fiber*: Fibers with silica content of 96%–99% are produced by leaching glass fibers. Such fibers provide excellent heat resistance, but relatively low strengths. They are usually used in short-fiber form for molding compounds.
2. *Silica or quartz fiber*: Fibers of pure silica provide optimum heat resistance (to about 93°C), although strength is somewhat lower than that of conventional E-glass.

3. *High modulus fibers*: Fibers of a beryllia-containing glass have been developed (primarily for filament winding use) with modulus of about 109,866–123,599 MPa.

Production Methods

Most fibrous glass is produced either by air, steam, or flame blowing or by mechanical pulling or drawing. Blowing produces relatively short staple fibers; mechanical drawing produces continuous monofilaments.

In blowing, steam or air jets impinge upon and breakup molten streams of glass, forming fibers. The type of fiber produced depends on the pressure of the steam or air and the temperature and viscosity of the molten glass.

In the mechanical drawing process, the molten glass is fed into a “bushing,” which contains a number of orifices through which the glass flows. Continuous filaments are then drawn from the molten stream. During the early stages of cooling, the stream is attenuated into filaments by being pulled at very high speeds—usually ranging from 25 to 50 m/s.

Insulation

In general, fibrous glass insulation is available in densities ranging from 0.5 to 12 lb/ft³. Maximum operating temperature is about 316°C–1093°C, depending on type of glass. It provides high sound absorption, relatively high tensile strength, and resistance to moisture, fire, rotting, and fungi and bacteria growth. It is available in either flexible or rigid form.

The excellent insulating properties of fibrous glass are due to the large pockets of air between the fibers. These air pockets take up considerable volume.

Fibrous glass is not affected by low temperatures and has been used satisfactorily at temperatures as low as –212°C. Heat resistance depends on type of glass: borosilicate glass is generally limited to operating temperatures of 316°C–538°C; high silica glasses are capable of operating at 999°C; silica (quartz) fibers are usable up to 1093°C. The heat resistance of bonded insulations is normally limited by the heat resistance of the binder (maximum, about 232°C–316°C).

Forms

Following are the various forms in which fibrous glass is used in reinforced plastics:

1. Rovings consist of a number of strands (usually 60) gathered together from cake packages and wound on a tube to form a cylindrical package. Rovings have very little or no twist. They are used either to provide completely unidirectional strength characteristics, such as in filament winding, or are chopped into predetermined lengths for preform-matched metal or spray molding.
2. Chopped strand consists of strands that have been cut into short lengths (usually 12.7–50.8 mm) in a manner similar to chopped roving, for use in preform-matched metal or spray molding, or to make molding compounds. It is the least expensive form of fibrous-glass reinforcement.
3. Milled fibers are produced from continuous strands that are hammer-milled into small modules of filamented

glass (nominal lengths of 0.8–3.2 mm). Largely used for filler reinforcement in casting resins and in resin adhesives, they provide greater body and dimensional stability.

4. Yarns are twisted from either filaments or staple fibers on standard textile equipment. Although primarily an intermediate form from which woven fabrics are made, yarns are used for making rod stock, and for some very high strength, unidirectionally reinforced shapes. A common form in which yarn is available is the “warp beam,” where many parallel yarns are wrapped on a mandrel.
5. Nonwoven mats are available both as reinforcing mats and as surfacing or overlay mats. Reinforcing mats are made of either chopped strands or swirled continuous strands laid down in a random pattern. Strands are held together by resinous binders. In laminates, mats provide relatively low strength levels, but strengths are isotropic. Surfacing or overlay mats are both thin mats of staple monofilaments. They provide practically no reinforcing, but serve to stabilize the surface resin coat, providing better appearance.
6. Woven fabrics and rovings provide the highest strength characteristics to reinforced plastic laminates (except for filament-wound structures), although strengths are orthotropic. A wide variety of fabrics and weaves are available both in woven yarns and woven rovings. Probably the most common types used are plain, basket, crowfoot satin, long shaft satin, unidirectional, and leno weaves.

Fibers Structure (Metals)

(1) In forgings, a structure revealed as laminations, not necessarily detrimental, on an etched section or as a ropy appearance on a fracture. It is not to be confused with silky or ductile fracture of a clean metal. (2) In wrought iron, a structure consisting of slag fibers embedded in ferrite. (3) In rolled steel plate stock, a uniform, fine-grained structure on a fractured surface, free of laminations or shale-type discontinuities.

Fibers Surface

A rough surface with linear features similar to rope.

Fick's Law

The quantity of atoms diffusing across a unit plane in unit time is inversely proportional to the concentration gradient.

Field Ion Microscopy

An analytical technique in which atoms are ionized by an electric field near a sharp specimen tip; the field then forces the ions to a fluorescent screen which shows an enlarged image of the tip, and individual atoms are made visible. See also *atom probe*.

Field Ionization

The ionization of gaseous atoms and molecules by an intense electric field, often at the surface of a solid.

Field-Emission Microscopy

An image-forming analytical technique in which a strong electrostatic field causes emission of electrons from a sharply rounded

point or from a specimen that has been placed on that point. The electrons are accelerated to a phosphorescent screen, or photographic film, producing a visible picture of the variation of emission over the specimen surface.

Field-of-View

The maximum diameter of an object that can be imaged by a microscope or other analytic technique.

Filament

The smallest unit of fibrous material. The basic units formed during drawing and spinning, which are gathered into strands of fiber for use as reinforcements. Filaments usually are of extreme length and very small diameter, usually less than 25 μm (1 mils). Normally, filaments are not used individually. Some textile filaments can function as a reinforcing yarn when they are of sufficient strength and flexibility.

Filament Winding

A process for fabricating a reinforced plastic or composite structure in which continuous reinforcements (filament, wire, yarn, tape, and the like), either previously impregnated with a matrix material or impregnated during the winding, are placed over a rotating and removable form or mandrel in a prescribed way to meet certain stress conditions. Generally, the shape is a surface of revolution and may or may not include end closures. When the required number of layers is applied, the wound form is cured and the mandrel is removed. See also *helical winding* and *polar winding*.

Filament-Wound Reinforced Plastics

The true fiberglass filament-wound structure may be more appropriately termed a resin-bonded filament-wound structure because it comprises approximately 80% glass fibers by weight and 20% bonding resin. Fibers are generally oriented to resist the principal stresses and the resin protects while secondarily supporting the fiber system. Filament winding is well adapted to the fabrication of internal pressure vessels; it has also performed well under external pressure and can be designed to function efficiently as a column or beam. This structure has the tensile strength of moderately heat-treated alloy steel and one-quarter of the weight.

The Winding Process

Bands of parallel glass filaments (usually in the form of roving) are wound over a mandrel following a precise pattern in such a way that subsequent bands lie adjacent, progressively covering the mandrel in successive layers, thus generating a shell structure. Liquid resin is simultaneously applied, generally by passing the filament band through a bath of catalyzed resin.

Tension generates a running load between the curved work surface and filament band which forces out air and excess resin and allows each successive layer ultimately to rest on solid material while the remaining interstices are filled with resin. Precision of filament placement plus tension and viscosity control are primary controlling factors in the attainment of high fiber content, which is generally desired for high strength.

Preimpregnation of the fiber strands is also used as a means of applying the resin binder. Such prepregs must fuse on contact with

F

the work to accomplish a bond so the fundamental relationships remain the same. The fiber bands are parallel strands only, because a cross weave or other structural filler would not bear primary loads and would preclude the true maintenance of equal tension on fibers in the band or roving when winding over crowned surfaces.

Tension serves only the purpose of accomplishing high fiber content and cannot be considered as accomplishing any prestressing. This is primarily true because the dry strength of glass fibers, as wound, is only about one-quarter of the ultimate resin consolidated strength. Also, unless some structural component is to remain within the wound shell (rather than a removable mandrel), there is no member against which a prestress can be maintained.

Range and Accuracy

Large or small structures are easily fabricated by adhering to the basic principles. Winding precision is important as is the relation of filament tension, resin viscosity, and radius of curvature of the filament path on the work surface. Small tubes have been made down to 0.65 cm in diameter, and there appear to be no fixed limitations in either direction. Wall thicknesses may be several centimeters or more because the normal bonding resins contain no volatile components and the glass content is so high that there is little danger of the exothermic heat becoming excessive.

Dimensional control in winding depends upon mandrel accuracy as well as both material and process control. The bands of filaments are generally 0.13 mm thick, and a full layer requires coverage by both right- and left-hand helices making the layer thickness 0.25 mm. Glass fiber thickness is subject to some variation, and resin content variation will also affect thickness. Wall thickness can generally be held to $\pm 5\%$. Length and diameter are easily held to 1/10% of 1% and less because there is little resin shrinkage or wound-in strain due to winding tension.

Machining may be accomplished by carbide tools or grinding techniques. Tolerances can be held as closely as in metals. The inner surface as-wound against a good steel mandrel can have a finish of approximately 30 $\mu\text{in.}$, and normal machining or grinding will produce a 40–60 $\mu\text{in.}$ finish. Cutting of surface fibers in machining does not weaken the structure.

Component Materials

There are three primary materials in this composite: the glass fiber, fiber finish, and the bonding resin. Glass fibers are continuous and each “end” contains 204 monofilaments approximately 0.01 mm in diameter. These ends are plied together without twist to form a strand of “roving”; 12-end, equally tensioned, roving is generally used for the winding of high-performance structures.

The fiber finish generally includes compounds with a chemical affinity for the glass surface and the bonding resin. These are called coupling agents. Other functional components are lubricants and “film formers” for the generation of strand integrity. Both improve handling properties but do not contribute to the performance of filament structures.

The resin binder materials are generally liquid at room temperatures or are wound hot for liquid integration of the system. Best results are obtained with strong tough resins such as the epoxies. Polyesters have also been extensively used (primarily for radomes where electrical properties are critical) and any bonding resin should be free of polymerization products of a volatile nature, which would have to escape through the cured structure.

Chemical resistance and electrical properties of the constituents are usually critical in selecting the proper resin, as applications of

the filament-wound structure are found in both the electrical and chemical industries.

Filamentary Shrinkage

A fine network of shrinkage cavities, occasionally found in steel castings, that produces a radiographic image resembling lace.

Filar Eyepiece

In an optical microscope, an eyepiece having in its focal plane a fiducial line that can be moved using a calibrated micrometer screw. Useful for accurate determination of linear dimensions. Also termed filar micrometer.

File Hardness

Hardness is determined by the use of a steel file of standardized hardness on the assumption that a material that cannot be cut with the file is as hard as, or harder than, the file. Files covering a range of hardnesses may be employed; the most common are files heat-treated to approximately 67–70 HRC.

Filiform Corrosion

Corrosion beneath surface coats, paint, etc., progressing as lines or fingers from initiation points which commonly are sites of coating breakdown or of precoat contamination.

Filigree

Delicate ornamental wire work.

Fill (Composites)

Reinforcing yarn oriented at right angles to the warp in a woven fabric.

Fill Density

See preferred term *apparent density*.

Fill Depth

Synonymous with *fill height*.

Fill Factor

In powder metallurgy, the quotient of the fill volume of a powder over the volume of the green compact after ejection from the die. It is the same as the quotient of the powder fill height over the height of the compact. Inverse parameter of *compression ratio*.

Fill Height

In powder metallurgy, the distance between the lower punch face and the top plane of the die body in the fill position of the press tool.

Fill Position

In powder metallurgy, the position of the press tool that enables the filling of the desired amount of powder into the die cavity.

Fill Ratio

See *compression ratio* (powder metallurgy).

Fill Shoe

See preferred term *feed shoe*.

Fill Volume

The volume that a metal powder fills after flowing loosely into a space that is open at the top, such as a die cavity or a measuring receptacle.

Fill-and-Wipe

Technique used with plastic parts that are molded with depressed designs; after application of paint, the surplus is wiped off, leaving paint only in the depressed areas. Sometimes called *wipe-ins*.

Filled Shell

See *atomic structure*.

Filler

(1) A relatively inert substance added to a plastic to alter its physical, mechanical, thermal, electrical, or other properties, or to lower cost or density. Sometimes, the term is used specifically to mean particulate additives. See also *inert filler* and *reinforced plastics*. (2) A relatively non-adhesive substance added to an adhesive to improve its working properties, permanence, strength, or other qualities. See also *binder* and *extruder*. (3) In lubrication, a substance such as lime, talc, mica, and other powders, added to a grease to increase its consistency or to an oil to increase its viscosity. (4) Additional material added in the molten state to a welded, brazed or soldered joint by a filler rod or by a consumable electrode. (5) Bulking material such as powder or fiber added to plastics.

Filler Metal

Metal added in making a brazed, soldered, or welded joint.

Filler Rod

Rod or wire melted in welding, brazing, or soldering processes to become incorporated in the joint. Filler rods are used in processes such as oxyacetylene acetylene welding or tungsten inert gas welding (T.I.G.) and are often held in one hand while the other holds the torch.

Filler Sheet

A sheet of deformable or resilient material that, when placed between the assembly to be adhesively bonded and pressure applicator, or when distributed within a stack of assemblies, aids in providing uniform application of pressure over the area to be bonded.

Fillet (Adhesive Bonding)

A rounded filling or adhesive that fills the corner or angle where two adherends are joined.

Fillet (Metals)

(1) Concave corner piece usually used at the intersection of casting sections. Also the radius of metal at such junctions as opposed to an abrupt angular junction. (2) A radius (curvature) imparted to inside needing surfaces.

Fillet Radius

Bend radius between two abutting walls.

Fillet Weld

A weld, approximately triangular in cross-section, joining two surfaces, essentially at right angles to each other in a lap, tee, or corner joint.

Fillet Weld Size

See preferred term *size of weld*.

Filling Yarn

The transverse threads or fibers in a woven fabric used in reinforced plastics or composites. Those fibers running perpendicular to the warp. Also called *weft*.

Film Adhesive

A synthetic resin adhesive, usually of thermosetting type, in the form of a thin, dry film of resin with or without a paper or glass carrier.

Film Resistance

The electrical resistance that results from films at contacting surfaces, such as oxides and contaminants, that prevent pure metallic contact.

Film Strength

An imprecise term denoting ability of a surface film to resist rupture by the penetration of asperities during sliding or rolling. A high film strength is primarily inferred from a high load-carrying capacity and is seldom directly measured. It is recommended that this term should not be used.

Film Stress

The compressive or tensile forces appearing in a film, such as internal film stress, which is the intrinsic stress of a film related to its mechanical structure and deposition parameters, or induced film stress, which is the component of film stress related to an external force such as mismatched mechanical properties of the substrate.

Film Thickness

In a dynamic seal, the distance separating the two surfaces that form the primary seal.

F

Filter

(1) A porous article or material for separating suspended particulate matter from liquids by passing the liquid through the pores in the filter and sieving out the solids. (2) Any transmission network used in electrical systems for the selective enhancement of a given class of input signals. Also known as electric filter; electric-wave filter. (3) A device employed to reject sound in a particular range of frequencies while passing sound in another range of frequencies. Also known as acoustic filter. (4) A semitransparent optical element capable of absorbing unwanted electromagnetic radiation and transmitting the remainder. A neutral density filter attenuates relatively uniformly from the ultraviolet to the infrared, but in many applications highly wavelength-selective filters are used. See also *neutral filter*.

Filter Fabrics

Any fabric used for filtering liquids, gases, or vapors, but, because of the heat and chemical resistance usually required, generally synthetic or metal fibers. Weave is an important consideration. Plain weave permits maximum interlacings, and a tight weave gives high impermeability to particles. Twill weave has lower interlacings in sharp diagonal lines and gives a more selective porosity for some materials. Satin weave has fewer interlacings, is spaced widely but regularly, and is used for dust collection and gaseous filtration.

Fibers are chosen for their particular chemical resistance, heat resistance, and strength. Dacron has good acid resistance except for concentrated sulfuric or nitric acid. It can be used to 325°F (162°C). High-density polyethylene has good strength and abrasion resistance, and its smooth surface minimizes clogging of the filter, but it has an operating temperature only to 230°F (110°C). Polypropylene can be used to 275°F (134°C). Nylon gives high strength and abrasion resistance. It has high solvent resistance, but low acid resistance. Its operating limit is about 250°F (121°C). Teflon is exceptionally resistant to a wide variety of chemicals. It can be operated above 400°F (204°C), and its waxy, non-sticking surface prevents clogging and makes it easy to clean, but the fiber is available only in single-filament form.

Filter Glass

See preferred term *filter plate*.

Filter Plate (Eye Protection)

An optical material that protects the eyes against excessive ultraviolet, infrared, and visible radiation.

Filter Sand

A natural sand employed for filtration, especially of water. Much of the specially prepared filter sand comes from New Jersey, Illinois, and Minnesota and is from ocean beaches, lake deposits, and sandbanks. The specifications for filter sand require that it be of fairly uniform size, free from clay and organic matter, and chemically pure, containing not more than 2% combined carbonates. The most common grain sizes are 0.014–0.026 in. (0.35–0.65 mm). Very fine sand clogs the filter. *Greensand*, produced from extensive beds in New Jersey, is used as a water softener. It is a type of marl classed as *zeolite* and consists largely of *glauconite*, which is a greenish granular mineral containing up to 25% iron, with a large percentage of silica and some potash and alumina. Synthetic zeolite is a *sodium alumina silicate* made by reacting caustic soda with bauxite

to form sodium aluminate and then reacting with sodium silicate. In addition to filtering, the greensand softener extracts the calcium and magnesium from the water.

Molecular sieves are synthetic crystalline zeolites whose molecules are arranged in a crystal lattice so that there are a large number of small cavities interconnected by smaller pores of uniform size, the network of cavities and pores being up to 50% of the volume of the crystal. This consists of three-dimensional frameworks of SiO_2 and AlO_4 tetrahedra. Electrovalence of each tetrahedron is balanced by the inclusion in the crystal of a metal cation of Na, Ca, or Mg.

Filtration

The separation of a liquid plus solid mixture by passing it through a filter. The liquid produced is the filtrate.

Fin

(1) Excess material left on a molded plastic object at those places where the molds or dies mated. Also, the web of material remaining in holes or opening in a molded part, which must be removed and finished. (2) Metal on a casting caused by an imperfect joint in the mold or die. (3) A thin projecting piece of material. It may be deliberate as in a cooling fin or it may be inadvertent for example, the fin or flash formed on a die forging at the interface of badly fitting dies.

Final Annealing

An imprecise term used to denote the last anneal given to a nonferrous alloy prior to shipment.

Final Density

The density of a sintered product.

Final Polishing

A polishing process in which the primary objective is to produce a final surface suitable for microscopic examination.

Fine Ceramics

Same as *advanced ceramics*.

Fine Gilt

A thin gold surface layer applied by coating items with a mercury gold amalgam and then heating them at about 360°C causing the mercury to evaporate leaving an adherent gold film.

Fine Gold

24 carat gold.

Fine Grain Steel

Steels having an intrinsic tendency to retain a fine austenitic grain size during normalizing and annealing at the temperature appropriate to the composition. The characteristic is common in steels deoxidized with aluminum which leaves a large quantity of very fine aluminum nitride particles which impede grain growth.

Fine Hackle

See *hackle*.

Fine Silver

Silver with a fineness of 999; equivalent to a minimum content of 99.9% Ag with the remaining content unrestricted.

Fineness

A measure of the purity of gold or silver expressed in parts per thousand.

Fines (Ceramics, Metals, Ores)

(1) The product that passes through the finest screen in sorting crushed or ground material. (2) Sand grains that are substantially smaller than the predominating size in a batch or lot of foundry sand. (3) The portion of a powder composed of particles smaller than a specified size, usually 44 μm (–325 mesh).

Fines (Plastics)

Very small particles (usually under 200 mesh) accompanying larger grains, usually of molding powder.

Finish (Composites)

A mixture of materials for treating glass or other fibers. It contains a coupling agent to improve the bond of resin to the fiber and usually includes a lubricant to prevent abrasion, as well as a binder to promote strand integrity. With graphite or other filaments, it may perform any or all of the above functions.

Finish (Metals)

(1) Surface condition, quality, or appearance of a metal. (2) Stock on a forging or casting to be removed and finish machining. (3) The forging operation in which the part is forged into its final shape in the finish die. If only one finish operation is scheduled to be performed in the finish die, this operation will be identified simply as finish; first, second, or third finish designations are so termed when one or more finish operations are to be performed in the same finish die.

Finish (Plastics)

To complete the secondary work on a molded plastic part so that it is ready for use. Operations such as filling, deflashing, buffing, drilling, tapping, and degating are commonly called finishing operations.

Finish Allowance

(1) The amount of excess metal surrounding the intended final configuration of a formed part; sometimes called forging envelope, machining allowance, or cleanup allowance. (2) Amount of stock left on the surface of a casting for machining.

Finish Annealing

A *subcritical annealing* treatment applied to cold-worked low- or medium-carbon steel. Finish annealing, which is a compromise

treatment, lowers residual stresses, thereby minimizing the risk of distortion in machining while retaining most of the benefits of machinability contributed by cold working. Compare with *final annealing*.

Finish Grinding

The final grinding action on a workpiece, of which the objectives are surface finish and dimensional accuracy.

Finish Machining

A machining process analogous to *finish grinding*.

Finish Trim

Flash removal from a forging; usually performed by trimming, but sometimes by hand sawing or similar techniques.

Finished Steel

Steel that is ready for the market and has been processed beyond the stages of billets, blooms, sheet bars, slabs, and wire rods.

Finisher (Finishing Impression)

The die impression that imparts the final shape to a forged part.

Finishing Die

The die set used in the last forging step.

Finishing Temperature

The temperature at which *hot working* is completed.

Finite Element Analysis

An important technique for determining the levels and distribution of stress in components. Its approach is to develop a mathematical model, in the form of a grid or mesh, which divides the structure into many small, simple segments, usually termed “elements.” These are analyzed individually and collectively, usually by powerful computer programs, to determine the stress induced in each element when a force is applied. The technique can deal with complex and cracked three-dimensional structures and components. See also *fracture mechanics*.

Fire Bars

The grading supporting a solid fuel fire.

Fire Box

The combination chamber of a fire tube boiler.

Fire Cracking

Cracking during heating.

F

Fire Extinguishers

Materials used for extinguishing fires, usually referring to chemicals in special containers rather than the materials, like water, used in quantity for cooling and soaking the fuel with a noncombustible liquid. There are three general types of fire extinguishers: those for smothering, such as carbon dioxide; those for insulating the fuel from the oxygen supply, such as licorice and protein foams, which also include mineral powders that melt and insulate metallic fires; and chemicals which react with the combustion products to terminate the chain reaction of combustion, such as *bromotri-fluoromethane*. CBrF_3 , a nontoxic colorless gas liquefied in cylinders. *Freon FE 130I*, of DuPont, is this chemical, while *Freon 13B1* of the same company is *monobromotrifluoromethane* gas pressurized with nitrogen. The relative effectiveness of extinguishers varies with the type of fuel in the fire, but on average, with bromotrifluoromethane taken as 100%, dibromodifluoromethane would be almost 67, the dry chemical sodium hydrogen carbonate 66, carbon tetrachloride 34, and carbon dioxide about 33. Others in the family include the *Halons*, halogenated hydrocarbons. *Halon 1211* is *bromochlorodifluoromethane*, *Halon 1301* is *bromotrifluoromethane*, *Halon CTFE* is *polychlorotrifluoroethylene*, and *Halon TFE* is *polytetrafluoroethylene*. The brominated compounds destroy stratospheric ozone even more drastically than do the *chlorofluorocarbons*, but since smaller quantities are released, their use is not being curtailed as severely as the CFCs.

Fire Point

The temperature at which a material will continue to burn for at least 5 s without the benefit of an outside flame.

Fire Scale

Intergranular copper oxide remaining below the surface of silver-copper alloys that have been annealed and pickled.

Fire Side Corrosion

Severe corrosion occurring on the fire side of, usually, a tube in a steam raising boiler or similar plant as a result of a reaction between the metal and the gas stream or more often, aggressive ash deposits on the surface.

Fire Tube Boiler

See *boiler tube*.

Fire Welding

See *forge welding*.

Fireclay

Clays that will withstand high temperatures without melting or cracking have been used for lining furnaces, flues, and for making firebricks and lining tiles. Common fireclays are usually *silicate of alumina*. Theoretically these clays contain 45.87% alumina and 54.13% silica, but in general they contain considerable iron oxide, lime, and other impurities. The clays are grouped as low-duty, intermediate-duty, high-duty, and super-duty. The low-duty has low alumina and silica with high impurities and is limited to a temperature of 1600°F (871°C). Standard types are good for temperatures

of 2400°F–2700°F (1316°C–1482°C), and the super-duty to temperatures of 2700°F–3000°F (1482°C–1649°C). Keown-Bern Clay should have a balanced proportion of coarse, intermediate, and fine grain sizes. Clays with an excess of silica are also used.

Firecracker Welding

A variation of the *shielded metal arc welding* process in which a length of covered electrode is placed along the joint in contact with the parts to be welded; during the welding operation, the stationary electrode is consumed as the arc travels the length of the electrode.

Fired Mold

A shell mold or solid mold that has been heated to a high temperature and is ready for casting.

Fire-Refined Copper

Copper that has been refined by the use of a furnace process only, including refinery shapes and, by extension, fabricators' products made therefrom. Usually, when this term is used alone it refers to fire-refined tough pitch copper without elements other than oxygen being present in significant amounts. Fire refining involves melting the metal first under oxidizing conditions to oxidize impurities and then under reducing conditions to reduce the excess oxygen.

Firing

The controlled heat treatment of ceramic ware in a kiln or furnace, during the process of manufacture, to develop the desired properties.

Firing Range

(1) The range of fired temperature within which a ceramic composition develops properties that render it commercially useful. (2) The time-temperature interval in which a porcelain enamel or ceramic coating is satisfactorily matured.

First Block, Second Block, and Finish

The forging operation in which the part to be forged is passed in progressive order through three tools mounted in one forging machine; only one heat is involved for all three operations.

First-Degree Blocking

An adherence between adhesively bonded surfaces under test of such degree that when the upper specimen is lifted, the lower specimen will cling thereto, but may be parted with no evidence of damage to either surface.

First-Order Transition

A change of state associated with crystallization, melting, or a change in crystal structure of a polymer.

Fir-Tree Crystal

A type of *dendrite*.

Fisheye (Metals)

An area on a steel fracture surface having a characteristic white crystalline appearance.

Fisheye (Weld Defect)

A discontinuity found on the fracture surface of a weld in steel that consists of a small pore or inclusion surrounded by an approximately round, bright area.

Fisheye Fracture

Subsurface fatigue cracks that have initiated failure by some other mechanism, perhaps simple overload but often brittle fracture. Against a contrasting surface texture, the dull concentric fatigue markings have a fisheye appearance. Note the potential confusion with *fisheyes*.

Fisheyes

Bright marks, typically a millimeter or two in diameter, observes also fracture surfaces and evidence of hydrogen embrittlement. The hydrogen embrittlement cracks may initiate other damage mechanisms including fatigue increasing the potential confusion with fish-eye fracture.

Fishmouthing

See *alligatoring*.

Fishscale

A scaly appearance in a porcelain enamel coating in which the evolution of hydrogen from the basis metal (iron or steel) causes loss of adhesion between the enamel and the basis metal. Individual scales are usually small, but have been observed in sizes up to 25 mm (1 in.) or more in diameter. The scales are somewhat like blisters that have cracked partway around the perimeter but still remain attached to the coating around the rest of the perimeter.

Fishtail

(1) In roll forging, the excess trailing end of a forging. It is often used, before being trimmed off, as a tong hold for a subsequent forging operation. (2) In hot rolling or extrusion, the imperfectly shaped trailing end of a bar or special section that must be cut off and discarded as mill scrap.

Fission

Splitting into y number of parts. See *nuclear*.

Fission Fragments

Subatomic particles resulting from nuclear fission. The term often implies larger particles such as nuclei comprising multiple protons and neutrons.

Fission Poisons

Materials and nuclear fuel, particularly those produced in the nuclear fission process, which have a high neutron capture cross section and hence wastefully absorbs neutrons which would otherwise contribute to the chain reaction.

Fission Products

Elements produced by the nuclear fission of the heavy elements such as uranium, usually elements of atomic number 34–58. The term often implies radioactive isotopes of these elements.

Fissure

A small crack-like weld discontinuity with only slight separation (opening displacement) of the fracture surfaces. The prefixes macro or micro indicate relative size.

Fit

The amount of clearance or interference between mating parts is called actual fit. Fit is the preferable term for the range of clearance or interference that may result from the specified limits on dimensions (limits of size): Referred to ANSI standards.

Fixed Oil

An imprecise term denoting an oil that is difficult to distill without decomposition.

Fixed Position Welding

Welding in which the work is held in a stationary position.

Fixed-Feed Grinding

Grinding in which the wheel was fed into the work, or vice versa, by given increments or at a given rate.

Fixed-Land Bearing

See *fixed-pad bearing*.

Fixed-Load or Fix-Displacement Crack Extension Force Curves

Curves obtained from a fracture mechanics analysis for the test configuration, assuming a fixed applied load or displacement and generating a curve of *crack extension force* vs. the *effective crack size* as the independent variable.

Fixed-Pad Bearing

An axial- or radial-load bearing equipped with fixed pads, the surfaces of which are contoured to promote hydrodynamic lubrication.

Fixture

A device designed to hold parts to be joined in proper relation to each other.

Fixture Time

The shortest time required by an adhesive to develop handling strength such that test specimens can be removed from fixtures, unclamped, or handled without stressing the bond and thereby affecting bond strength. Also referred to as set time.

F

Fixturing

The placing of parts to be heat-treated in a constraining or semi-constraining apparatus to avoid heat-related distortions. See also *racking*.

Flake (Metals)

A short, discontinuous internal crack in ferrous metals attributed to stresses produced by localized transformation and hydrogen-solubility effects during cooling after hot working. In fracture surfaces, flakes appear as bright, silvery areas with a coarse texture. In deep acid-etched transverse sections, they appear as discontinuities that are usually in the midway to center location of the section. Also termed hairline cracks and shatter cracks. Also termed *fisheyes* when they are exposed on a fracture surface.

Flake (Plastics)

A term used to denote the dry, unplasticized base of cellulosic plastics.

Flake Graphite

Graphitic carbon, in the form of platelets, occurring in the microstructure of *gray iron*.

Flake Powder

A flat or scale-like particles whose thickness is small compared to the other dimensions.

Flaking

(1) The removal of material from a surface in the form of flakes or scale-like particles. (2) A form of pitting resulting from fatigue. See also *spalling*.

Flame Annealing

Annealing in which the heat is applied directly by a flame.

Flame Cleaning

The use of a soft, broad, oxy-fuel gas flame to remove deposits of paint, grease, rust, etc., from components of large structures prior to painting.

Flame Cutting

Processes utilizing a torch similar to that used for gas welding but in which the primary cutting action is the chemical reaction of the material with oxygen. A fuel gas is also involved but its main contribution is to raise the component to reaction temperature at the commencement of the cut. See also preferred term *oxy (gen) cutting*.

Flame Gouging

See *gouging*.

Flame Hardening

A process for hardening the surfaces of hardenable ferrous alloys in which an intense flame is used to heat the surface layers above the upper transformation temperature, whereupon the workpiece is immediately quenched.

Flame Plating

A process in which an oxy-acetylene mixture carrying a suspension of powdered refractory material is detonated to project the powder at high temperature and high velocity onto the surface to be coated.

Flame Resistance

Ability of a material to extinguish flame once the source of heat is removed. See also *self-extinguishing resin*.

Flame Retardants

Certain chemicals that are used to reduce or eliminate the tendency of a resin to burn.

Flame Scaling

(1) Descaling by a process similar to flame cleaning. (2) Flame heating freshly galvanized steel wire to promote intermetallic bonding and improve surface finish.

Flame Spraying

Thermal spraying in which a coating material is fed into an oxyfuel gas flame, where it is melted. Compressed gas may or may not be used to atomize the coating material and propel it onto the substrate. The sprayed material is originally in the form of wire or powder. See the terms *powder flame spraying* and *wire flame spraying*. The term flame spraying is usually used when referring to a combination-spraying process, as differentiated from *plasma spraying*.

Flame Spraying (Plastics)

Method of applying a plastic coating in which finely powdered fragments of the plastic, together with suitable fluxes, are projected through a cone of flame onto a surface.

Flame Straightening

Correcting distortion in metal structures by localized heating with a gas flame.

Flame Temperature

The maximum temperature within a flame.

Flame Treating (Plastics)

A method of rendering inert thermoplastic objects receptive to inks, and lacquers, paints, adhesives, and so forth, in which the object is bathed in an open flame to promote oxidation of the surface of the article.

Flame-Sprayed Coatings

Processes

Flame-spraying methods are used to produce coatings of a wide variety of heat-fusible materials, including metals, metallic compounds, and ceramics. There are three basic flame-spray processes.

Wire-Type Guns

These guns are used to produce coatings of metals, alloys, and, in some cases, ceramics. With this type of equipment, wire or rod from 0.76 to 4.7 mm in diameter is fed axially through the center of a fuel gas/O₂ flame at a controlled rate. The flame is surrounded by an annular blast of air, which imparts high velocity to the burning gases and provides the kinetic energy needed to atomize the metal as it melts. Acetylene is the most commonly used fuel gas, although propane, natural gas, and H₂ are also used.

Wire-type guns are the most widely used, because of their versatility and ease of operation.

Handheld guns are used to coat large areas such as bridges, ship hulls, and tanks. Machine-mounted guns are used principally for machine element applications, as in surfacing rolls or salvaging journals by building up worn areas. In many production applications, one or more electronically controlled guns are operated and cycled automatically by a central console.

Powder-Type Guns

A variety of materials that cannot be readily produced in the form of wire or rod utilize this type of gun. The guns are also used for spraying low-melting metals that are readily available in powder form.

With the powder gun, metal or ceramic powders are fed axially through a fuel gas/O₂ flame at a controlled rate. The powders are entrained in a carrier gas, which may be air, acetylene, or O₂. Because the powders are finely divided and dispersed as they enter the flame, further atomization is not required and annular air blast is not needed.

The powder supply for guns of this type may be a reservoir connected to the gun by a powder tube or hose, or it may be a canister attached directly to the gun.

Powder guns are used for flame-spraying a wide variety of ceramics, and for coating with “self-fluxing” alloys, which are subsequently fused to the base material. They have also been used for many years to apply zinc and aluminum coatings for corrosion prevention.

Plasma Guns

The plasma flame is produced by passing suitable gases through a confined arc, where dissociation and ionization occur. The ionized gases form a conductive path within a water-cooled nozzle, so that an arc of considerable length is maintained. The gases most commonly used are N₂, H₂, and argon.

Temperature of the plasma flame depends on the type and volume of gas used, the size of the nozzle, and the amount of current used. For flame-spraying purposes temperature ranges of 5482.4°C–8232.4°C are generally employed, although much higher temperatures may be attained if desired. Plasma flame-spray guns usually operate at 20–40 kW, using 47–141 L/min of gas.

In addition to their high-temperature capabilities, plasma guns have other advantages. Extremely high velocities are possible, and favorable environmental conditions can be obtained by proper

selection of gases. Spraying within a controlled atmosphere chamber permits the production of oxide-free coatings.

With the plasma gun, metal or ceramic powders are fed into the flame at a point downstream from the actual arc path. Current, gas flow, and powder flow must be adjusted for different coating materials, many of which would otherwise be completely vaporized.

Surface Preparation

Regardless of the flame-spray method used or the type of coating material being applied, some sort of surface preparation is usually required. Bond to the base is often largely mechanical, and, in general, the greater the degree of surface roughness, the better the bond. Thin coatings require less elaborate preparation than thick coatings, and some coating materials require much more thorough preparation than other materials.

Bonding methods used include abrasive blasting, rough threading, molybdenum bonding coats, heating, or combinations of these steps. Abrasive blasting is probably the most widely used.

Finishing Methods

Flame-sprayed deposits may be finished by machining or by grinding, depending on the hardness of the particular coating material. Sintered carbide tools are generally used for machining because even the softer materials contain some amount of abrasive oxides that may cause rapid wear of tool steel. For those materials that must be finished by grinding, specific wheel recommendations are available from flame-spray equipment manufacturers.

Flame-sprayed coatings may require sealing, depending on the type of coating and service requirements. A wide variety of impregnants are used to reduce porosity, enhance physical properties, or to improve friction characteristics.

Flammability

Measure of the extent to which a material will support combustion.

Flange

A projecting rim or edge of a part; usually narrow and of approximately constant width for stiffening or fastening. Usually perpendicular to the principal axis and often applied to tubes.

Flange (d) Joint

A joint formed between two components one or both of which is flanged. The joint may be made by bolting, welding, or brazing.

Flange Weld

A weld made on the edges of two or more members to be joined, usually light gage metal, at least one of the members being flanged. Flange weld, flare-bevel, and flare-V-groove welds may be confused because they have similar geometry before welding. A flange is welded on the edge and a flare is welded in the groove. See the term edge-flange weld which compares *flange*, *flare-bevel*, and *flare-V-groove welds*.

F

Flank

The end surface of a tool that is adjacent to the cutting edge and below it when the tool is in a horizontal position, as for turning. See *single-point tool*.

Flank Wear

The loss of relief on the flank of the tool behind the cutting edge due to rubbing contact between the work and the tool during cutting; measured in terms of linear dimension behind the original cutting edge. See the term *crater wear*.

Flapping

In copper refining, hastening oxidation of molten copper by striking through the slag-covered surface of the melt with a *rabble* just before the bath is poled.

Flare Test

A test applied to tubing, involving tapered expansion over a cone. Similar to *pin expansion test*.

Flare-Bevel Groove Weld

A weld in a groove formed by a member with a curved surface in contact with a planar member. Compare with *flange weld*. See also the term *edge-flange weld*.

Flare-V-Groove Weld

A weld in a groove formed by two members with curved surfaces. Compare with *flange weld*. See the term *edge-flange weld*.

Flaring

- (1) Forming an outward acute-angle flange on a tubular part.
- (2) Forming a flange by using the head of a hydraulic press.

Flash (Metals)

(1) In forging, metal in excess of that required to fill the blocking or finishing forging impression of a set of dies completely. Flash extends out from the body of the forging as a thin plate at the line where the dies meet and is subsequently removed by trimming. Because it cools faster than the body of the component during forging, flash can serve to restrict metal flow at the line where dies meet, thus ensuring complete filling of the impression. See also *closed-die forging*. (2) In casting, a fin of metal that results from leakage between mating mold surfaces. (3) In welding, the material which is expelled or squeezed out of a weld joint and which forms around the weld.

Flash (Plastics)

The portion of the charge that flows from or is extruded from the mold cavity during the molding. Extra plastic attached to a molding along the parting line, which must be removed before the part is considered finished.

Flash Anneal

Annealing of short duration applied to wire or thin sheet.

Flash Coat

A thin metallic coating usually less than 0.05 mm (0.002 in.) in thickness.

Flash Extension

That portion of *flash* remaining on a forged part after trimming; usually included in the normal forging tolerances.

Flash Land

Configuration and the blocking or finishing impression of forging dies designed to restrict or to encourage the growth of *flash* at the parting line, whichever may be required in a particular case to ensure complete filling of the impression.

Flash Line

The line left on a forging after the flash has been trimmed off.

Flash Mold (Plastics)

A mold in which the mold faces are perpendicular to the clamping action of the press, so that the greater the clamping force, the tighter the mold seam.

Flash Plate

A very thin final electrode deposited film of metal.

Flash Point

(1) The temperature to which a material must be heated to give off sufficient vapor to form a flammable mixture. (2) The lowest temperature at which the vapor of a lubricant can be ignited under specified conditions.

Flash Temperature

The maximum local temperature generated at some point in a sliding contact. The flash temperature occurs at areas of real contact due to the frictional heat dissipated at these areas. The duration of the flash temperature is often of the order of a microsecond. The term flash temperature may also mean the average temperature over a restricted contact area (for example, between gear teeth).

Flash Weld

A weld made by *flash welding*.

Flash Welding

A resistance welding process that joins metals by first heating abutting surfaces by passage of electric current across the joint, then forcing the surfaces together by the application of pressure.

Flashing and upsetting are accompanied by expulsion of metal from the joint.

Flash (Butt) Welding

An electric welding process in which the joint faces are first brought together to strike an arc and then held in light contact or even drawn slightly apart to allow heating before they are finally forced together again. It is essentially a pressure weld as any molten metal is injected in the final closure. See preferred term *flash welding*.

Flashback

A recession of the welding or cutting torch flame into or back of the mixing chamber of the torch.

Flashback Arrestor

A device incorporated into an oxygen or oxyfuel welding or cutting torch to limit damage from a *flashback* by preventing propagation of the flame front beyond the point at which the arrestor is installed.

Flashing

In *flash welding*, the heating portion of the cycle, consisting of a series of rapidly recurring localized short-circuits followed by molten metal expulsions, during which time the surfaces to be welded are moved one toward the other at a predetermined speed.

Flashing Time

The time during which the flashing action is taking place in *flash welding*.

Flash-Off Time

See preferred term *flashing time*.

Flashover

The passage of electric current across the surface of an insulator.

Flask

(1) Any vessel for containing fluid. (2) In the context of nuclear waste transportation, a metal vessel of massive proportions, high integrity and tightly sealed. (3) A metal or wood frame used for making and holding a sand mold. The upper part is called the *cope*; the lower, the *drag*. See the term *blind riser*.

Flat Drill

A rotary end-cutting tool constructed from a flat piece of material, provided with suitable cutting lips at the cutting end. See also the term *drill*.

Flat Edge Trimmer

A machine for trimming notched edges on shells. The slide is cam driven so as to obtain a brief dwell at the bottom of the stroke, at

which time the die, sometimes called a shimmy die, oscillates to trim the part.

Flat Fracture

A fracture surface approximately perpendicular to the principal stress and substantially level. The fracture mode may be crystalline, as in a brittle fracture, or it may comprise multiple, microscopic ductile shear dimpled fractures. The term may be used in contrast to ductile or sheer fracture where the fracture mode is ductile shear but the plane of fracture is at approximately 45° to the principal stress.

Flat Glass

A general term covering sheet glass, plate glass, and various forms of rolled glass.

Flat Position Welding

The position in which the components being welded and, or the weld surface are approximately horizontal and the weld is made from above. This is usually taken to mean a weld slope not greater than 5° and a weld rotation not greater than 10°. Down hand position is the same. See term *welding position*.

Flat Wire

A roughly rectangular or square mill product, narrower than *strip*, in which all surfaces are rolled or drawn without any previous slitting, shearing, or sawing.

Flat-Die Forging

Forging metal between flat or simple-contour dies by repeated strokes and manipulation of the workpiece. Also known as *open-die forging*, *hand forging*, and *smith forging*.

Flats

(1) A longitudinal, flat area on a normally convex surface of a protruded plastic, caused by shifting of the reinforcement, lack of sufficient reinforcement, or local fouling of the die surface. (2) An imprecise term usually indicating rolled steel products 3–6 mm thick and up to about 600 mm wide.

Flattening

(1) A preliminary operation performed on forging stock to position the metal for a subsequent forging operation. (2) The removal of irregularities or distortion in sheets or plates by a method such as *roller leveling* or *stretcher leveling*.

Flattening Dies

Dies used to flatten sheet metal hems; that is, dies that can flatten a bend by closing it. These dies consist of a top and bottom die with a flat surface that can close one section (flange) to another (hem, seam): See the term *press-brake forming*.

Flattening Mill

A rolling mill producing sheet metal.

F

Flattening Test

A test in which a hollow component, weld, tube, etc., is flattened to a specified degree that may or may not be in contact with internal surfaces. Acceptance criteria depends on the application but usually specifies limitations on cracking.

Flaw

A nonspecific term often used to imply a crack-like discontinuity. See also preferred terms *discontinuity*, *imperfection*, and *defect*.

Flaw Detection

Any technique for detecting defects such as cracks and voids. See *nondestructive testing*.

Flax

A fiber obtained from the flax, or linseed, plant, *Linum usitatissimum*, used for making the fabrics known as linens and for thread, twine, and cordage. It is valued because of its strength and durability. It is finer than cotton and very soft, and the fibers are usually about 20 in. (50.8 cm) long. Flax consists of the **bast fibers**, or those in the layer underneath the outer bark, which are of fine texture. The plants are pulled up by the roots, retted, or partly decayed, scraped, and the fibers combed out and bleached in the sun. The plants that are grown for the oil seed yield a poor fiber and are not employed to produce flax.

Flex

(1) Flexible insulated cable for conducting electricity particularly for domestic equipment. (2) Bend usually with the implication that the degree of bending is within the elastic range so that a component returns to shape following removal of load.

Flex Roll

A movable jump roll designed to push up against a metal sheet as it passes through a roller leveler. The flex roll can be adjusted to deflect the sheet any amount up to the roll diameter.

Flex Rolling

Passing metal sheets through a flex roll unit to minimize yield-point elongation in order to reduce the tendency for *stretcher strains* to appear during forming.

Flexibility

The quality or state of a material that allows it to be flexed or bent repeatedly without undergoing rupture. See also *flexure*.

Flexibilizer

An additive that makes a finished plastic more flexible or tough. See also *plasticizer*.

Flexible Cam

An adjustable pressure-control cam of spring steel strips used to obtain varying pressure during a forming cycle.

Flexible Hinge

See *flexure pivot bearing*.

Flexible Manufacturing System

A number of machines and other plant items, often computer-controlled, that can be readily arranged and utilized to produce a variety of components.

Flexible Molds

Molds made of rubber or elastomeric plastics, used for casting plastics. They can be stretched to remove cured pieces having undercuts.

Flexural Failure

A material failure caused by repeated flexing.

Flexural Modulus

The ratio, within the elastic limit, of the applied stress on a reinforced plastic test specimen in flexure to the corresponding strain in the outermost fibers of the specimen.

Flexural Strength

(1) A property of solid material that indicates its ability to withstand a flexural or transverse load. (2) The tensile strength and related properties deduced from bending tests. Brittle materials likely to break in the grips of a tensile machine are often tested in this matter.

Flexural Strength (Composites)

The maximum stress that can be borne by the surface fibers in a beam in bending. The flexural strength is the unit resistance to the maximum load before failure by bending, usually expressed in force per unit area.

Flexure

A term used in the study of strength of materials to indicate the property of a body, usually a rod or beam, to bend without fracture. See also *flexibility*.

Flexure Pivot Bearing

A type of bearing guiding the moving parts by flexure of an elastic member or members rather than by rolling or sliding. Only limited movement is possible with a flexure pivot.

Flexure Stress (Glass)

The tensile component of the bending stress produced on the surface of a glass section opposite to that experiencing a locally impinging force.

Flint

Flint is SiO₂ and is a black, gray, or brown cryptocrystalline variety of quartz. In the United States, ceramists often employ the term *flint* to include other siliceous minerals in addition to true flint.

Calcined and ground flint is used in pottery to reduce shrinkage in drying and firing and to give the body a certain rigidity. Flint is employed in the manufacture of whiteware, such as fine earthenware, bone china, and porcelain.

An opaque variety of *chalcedony* or nearly pure amorphous *quartz* which shows no visible structure. It is deposited from colloidal solution and is an intimate mixture of quartz and opal. It contains 96%–99% silica and may be colored to dull colors by impurities. Thin plates are translucent. When heated, it becomes white. Flint is finally crystalline. It breaks or chips with a convex, undulating surface. The hardness is Mohs 7, and the specific gravity is 2.6. It was the prehistoric utility material for tools, and was later used with steel to give sparks on percussion. *Gun flints* are still made from a type of flint mined at Brandon, England, for special uses. *Lydian stone*, or *touchstone*, was a cherry flint used for testing gold. Flint is now chiefly used as an abrasive and in pottery and glass manufacture. *Flint paper* for abrasive use contains crushed flint grades from 20 to 240 mesh. Flint is also used in the form of grinding pebbles. *Potters' flint*, used for mixing in ceramics to reduce the firing and drying shrinkage and to prevent deformation, is ground flint of about 140 mesh made from white *French pebbles*.

Flotation

A technique for separating material suspended in a liquid, in particular to concentrate the mineral content of ores. The fine particulate ore is mixed into the fluid with oil or similar agent in the mixture and agitated. The oil attaches to the mineral and air bubbles assist in floating the particle to the surface where it is retained by surface tension before being skimmed off.

The concentration of valuable minerals from ores by agitation of the ground material with water, oil, and floatation chemicals. The valuable minerals are generally wetted by the oil, lifted to the surface by clinging air bubbles, and then floated off.

Floating Bearing

A bearing designed or mounted to permit axial displacement between shaft and housing.

Floating Chase

In forming of plastics, a mold member, free to move vertically, that fits over a lower plug or cavity, and into which an upper plug telescopes.

Floating Die

(1) In metal forming, a die mounted in a die holder or punch mounted in its holder such that a slight amount of motion compensates for tolerance of the die parts, the work, or the press. (2) A die mounted on heavy springs to allow vertical motion in some trimming, shearing, and forming operations.

Floating Die Pressing

The compaction of a metal powder in a floating die, resulting in densification at opposite ends of the compact. Analogous to double action pressing.

Floating Plug

In tube drawing, an unsupported mandrel that locates itself at the die inside the tube, causing a reduction in wall thickness while the die is reducing the outside diameter of the tube.

Floating-Ring Bearing

A type of journal bearing that includes a thin ring between the journal and the bearing. The ring floats and rotates at a fraction of the journal rotational speed.

Flocculant

An electrolyte added to a colloidal suspension to cause the particles to aggregate and settle out as a result of reduction in repulsion between the particles.

Flocculate

A grouping of primary particles, aggregates, or agglomerates having weaker bonding than either the aggregate or agglomerate structures. Flocculates are usually formed in a gas or liquid suspension and those formed in a liquid can generally be broken up by gentle shaking and stirring.

Flocculation

Agglomeration of particles in a suspension causing them to settle out.

Flock

A material obtained by reducing textile fibers to fragments as by cutting, tearing, or grinding, to give various degrees of comminution. Flock can either be fibers in entangled, small masses or beads, usually of irregular broken fibers, or comminuted (powdered) fibers.

Flock Point

A measure of the tendency of a lubricant to precipitate wax or other solids from solution. Depending on the test used, the flock point is the temperature required for precipitation, or the time required at a given temperature for precipitation.

Flocking

A method of coating by spraying finely dispersed textile powders or fibers.

Flong Papier-Mâché (Pulped Paper)

Used as a molding material forecasting low melting-point metals, in particular tin-based printer-type metals.

Flood Lubrication

A system of lubrication in which the lubricant is supplied in a continuous stream at low pressure and subsequently drains away. Also known as *bath lubrication*.

F

Floor Molding

In foundry practice, making sand molds from loose or production patterns of such size that they cannot be satisfactorily handled on a bench or molding machine, the equipment being located on the floor during the entire operation of making the mold.

Flop Forging

A forging in which the top and bottom die impressions are identical, permitting the forging to be turned upside down during the forging operation.

Floppers

On metals, lines or ridges that are transverse to the direction of rolling and generally confined to the section midway between the edges of a coil as rolled.

Flospinning

Forming cylindrical, conical, and curvilinear shaped parts by power spinning over a rotating mandrel. See also *spinning*.

Flow

Movement (slipping or sliding) of essentially parallel planes within an element of a material in parallel directions; occurs under the action of *shear stress*. Continuous action in this matter, and at constant volume and without disintegration of the material, is termed *yield*, *creep*, or *plastic deformation*.

Flow (Adhesives)

Movement of an adhesive during the bonding process, before the adhesive is set.

Flow (Plastics)

The movement of resin under pressure, allowing it to fill all parts of a mold.

Flow Brazing

Brazing by pouring hot molten nonferrous filler metal over a joint until the brazing temperature is attained. The filler metal is distributed in the joint by capillary action.

Flow Brightener

(1) Melting of an electrodeposit, followed by solidification, especially of tin plate. (2) Fusion (melting) of a chemically or mechanically deposited metallic coating on a substrate, particularly as it pertains to soldering. (3) It is practiced on electrodeposited tin coatings on steel or copper base items.

Flow Cavitation

Cavitation caused by a decrease in static pressure induced by changes in the velocity of a flowing liquid. Typically this may be caused by flow around an obstacle or through a constriction, or relative to a blade or foil.

Flow Factor

See preferred term *flow rate*.

Flow Lines

(1) Texture showing the direction of metal flow during hot or cold working. Flow lines can often be revealed by etching the surface or a section of a metal part. (2) In mechanical metallurgy, paths followed by minute volumes of metal during deformation. (3) The lines on a polished and etched section through a raw material that reveals the deformation pattern during previous working operations. They are caused by the varying etching characteristics of areas with minor differences in composition or by lines of inclusions. See also *sulfur print* in *nature print*.

Flow Marks

Wavy surface appearance of an object molded from thermoplastic resins, caused by improper flow of the resin into the mold.

Flow Meter

(1) A device for indicating the rate of gas flow in a system. (2) In powder metallurgy, a metal cylinder whose interior is funnel shaped and whose bottom has a calibrated orifice of standard dimensions to permit passage of a powder and the determination of the *flow rate*.

Flow Molding

The technique of producing leather-like materials by placing a die-cut plastic blank (solid or expanded vinyl or vinyl-coated substrate) in a mold cavity (usually silicone rubber molds) and applying power via a high-frequency radio frequency generator to melt the plastic such that it flows into the mold to the desired shape and with the desired texture.

Flow Rate

The time required for a metal powder sample of standard weight to flow through an orifice in a standard instrument according to a specified procedure.

Flow Soldering

See *wave soldering*.

Flow Spinning

See *spinning*.

Flow Stress

The true stress at which plastic strain commences. It is increased by prior plastic strain. Flow stress and fracture stress both fall as temperature rises but the rates of fall may differ. Some materials, for example steel, have a flow stress higher than the fracture stress at low temperature but the reverse at higher temperatures. Thus at low temperatures they fracture before plastic strain can commence, that is, they fail in a brittle manner but at the higher temperatures they plastically deform before failing, i.e., they behave in a ductile matter. See *tensile test*.

Flow Test

A standardized test to measure how readily a metal powder flows. See also *flow rate*.

Flow Through

A forging defect caused by metal flow past the base of a rib with resulting rupture of the grain structure.

Flow Welding

(1) A welding process that produces coalescence of metals by heating them with molten filler metal poured over the surfaces to be welded until the welding temperature is attained and until the required filler metal has been added. The filler metal is not distributed in the joint by capillary action. (2) A process in which bulk molten metal is poured into the joint gap which is usually of substantial width. The weld metal needs sufficient superheat to melt the joint faces to form a fusion weld. Alternatively, the weld metal may be allowed to overflow to waste until the joint faces have fused sufficiently. See also *burning*, *burning on*, and *thermic welding*.

Flowability

(1) In casting, a characteristic of a foundry sand mixture that enables it to move under pressure or vibration so that it makes intimate contact with all surfaces of the pattern or core box. (2) In welding, brazing, or soldering, the ability of molten filler metal to flow or spread over a metal surface.

Flower (s)

The bright spangle on hot dip galvanized components.

Fluid

Any liquid or gas. Its shape is defined by the containment vessel.

Fluid Bearing

See *hydrostatic bearing*.

Fluid Erosion

See *liquid impingement erosion*.

Fluid Forming

A modification of the *Guerin process*, fluid forming differs from the fluid-cell process in that the die cavity, called a pressure dome, is not completely filled with rubber, but with hydraulic fluid retained by cup-shaped rubber diaphragm. See also *rubber-pad forming*.

Fluid Friction

Frictional resistance due to the viscous or rheological flow of fluids.

Fluid Lubrication

The condition where closely approaching surfaces in relative motion are maintained apart by a film of fluid lubricant. See *oil wedge*.

Fluid-Cell Process

A modification of the *Guerin process* for forming sheet metal, the fluid-cell process uses higher pressure and is primarily designed for forming slightly deeper parts, using a rubber pad as either the die or punch. A flexible hydraulic fluid cell forces an auxiliary rubber pad to follow the contour of the form block and exert a nearly uniform pressure at all points on the workpiece. See also *fluid forming* and *rubber-pad forming*.

Fluidity

- (1) The ability of liquid metal to run into and fill a mold cavity.
- (2) The reciprocal of *viscosity*.

Fluidized Bed

A bath of granular material through which gas is blown, usually via a porous bottom plate, to make the material flow like a liquid. For heat treatment applications the component is quenched into the bed to achieve fairly high rates of heat transfer, similar to an oil bath but cleaner. The gas may be air or an inert gas. Fluidized beds are also utilized as a combustion device in which coal particles are fluidized and burned by the injected air.

Fluidized-Bed Coatings

The fluidized-bed process is used to apply organic coatings to parts by first preheating the parts and then immersing them in a tank of finely divided plastic powders which are held in a suspended state by a rising current of air. In this suspended state, the powders behave and feel like a fluid. The method produces an extremely uniform, high-quality, fusion bond coating that offers many technical and economic advantages.

Fusion bond coatings are generally applied to metal parts, although other substrates have been successfully coated. The major fields of application are electrical, chemical, and mechanical equipment as well as household appliances. The process is now being used in every major industrial country in the world for applying many different plastics to a variety of parts.

Coating Application

Objects to be coated are preheated in an oven to a temperature above the melting point of the plastic coating material. The preheat temperature depends on the type of plastic used, the thickness of the coating to be applied, and the mass of the article to be coated.

After preheating, the parts are immersed with suitable motion in the fluidized bed. Air used to fluidize the plastic powders enters the tank through a specially designed porous plate located at the bottom of the unit.

When the powder particles contact the heated part, they fuse and adhere to the surface, forming a continuous and extremely uniform coating. In many cases, the part is postheated to coalesce the coating completely and improve its appearance. Thickness of the coating depends on the temperature of the part surface and how long it is immersed in the fluidized bed.

Coating Types

Cellulosic

Cellulosic fluidized-bed coatings are noted for their all-around combination of properties and are especially popular for decorative/protective applications. They combine good impact and abrasion

F

resistance with outstanding electrical insulation. The coatings have excellent weathering properties, salt-spray resistance, high gloss, and can be made in an almost unlimited range of colors. They can be solvent-etched to provide a satin finish and heat-embossed for additional effects.

The economy of cellulosic coatings combined with their excellent appearance and durability are particularly useful for such applications as indoor and outdoor furniture, kitchen fixtures, home and marine hardware, metal stampings, fan guards, and sporting goods. Major uses of cellulosic fusion bond finishes are coated transformer tanks and covers, reclosure tanks and covers, outdoor electrical equipment housings, and many pole line hardware parts.

Vinyl

Vinyl fluidized-bed coatings have a good combination of chemical resistance, decorative appeal, flexibility, toughness, and low-frequency insulating properties. They have excellent salt-spray resistance, outstanding outdoor weathering characteristics, and can be used for general-purpose electrical insulation. The vinyl fusion bond coatings are claimed to have better uniformity and edge coverage than plasticol coatings.

Fusion bond vinyl coatings have been especially successful on wire goods for applications such as dishwasher racks, washing-machine parts, and refrigerator shelves. They are also being used on wire furniture and hardware, and in industrial applications such as bus bars, pump impellers, transformer tanks and covers, auto battery brackets, conveyor rollers, and other material-handling equipment. Cast iron, die castings, and expanded metal parts can be readily coated.

Epoxy

Both thermoplastic and thermosetting materials can be applied. Epoxy coatings have a smooth, hard surface and exceptionally good electrical-insulation properties over a wide temperature range. They are available in rigid and semiflexible variations with different combinations of electrical, physical, and chemical properties. Epoxy coatings on electrical motor laminations provide good dielectric strength and uniform coverage over sharp edges. When properly applied, epoxy coatings have good impact resistance and do not sacrifice toughness for surface hardness. Other electrical applications include toroidal cores, wound coils, encapsulated printed circuit boards, bus bars, watt hour meter coils, resistors, and capacitors.

Nylon

The combination of properties that have made the polyamide plastics unique for molded and extruded parts are obtainable in coatings, and nylon used as a solution coating technique applied by the fluidized-bed process offers many advantages to the design engineer.

Nylon fusion bond finishes combine a decorative, smooth, and glossy appearance with low surface friction and excellent bearing and wear properties. They minimize scratching and cut down undesirable noise. The frictional heat developed on nylon is dissipated more rapidly when used as a coating over a conductive metal surface than when used as a solid plastics member. Coated metal parts offer increased dimensional stability. Because of the unique properties of nylon-coated metal parts, many users of the process are able to reduce the number of metal component parts at substantial savings.

By an additional immersion of the heated and coated part into a fluid bed of whirling molybdenum sulfide or graphite, an impregnated nylon surface can be produced with unusual bearing, frictional, and wear characteristics.

Nylon fusion bonds are effectively used in machine shop fixtures, modern indoor furniture to simulate a wrought iron finish, aircraft instrument panels, ball-joint suspensions, collars, guards, and slide valves used in textile and farm equipment, knitting machine parts, switch box cover panels, tractor control handles, and radar and calculator component parts.

Polyethylene

Polyethylene coatings combine low water absorption and excellent chemical resistance with good electrical insulation properties. They can be applied successfully in thicknesses of 10–60 mils by the fluidized-bed process. The primary uses for polyethylene coatings are for protecting chemical processing equipment and on food-handling equipment. Typical chemical applications include pipe and fittings, pump and motor housings, valves, battery hold-downs, fans, and electroplating jigs.

Chlorinated Polyether

This fluidized-bed coating has an excellent combination of mechanical, chemical, thermal, and electrical properties. It has good resistance to wear and abrasion. It provides good electrical insulation even under high humidity and high temperature conditions, and has very low moisture absorption. It can be used continuously at 121°C and even up to 149°C.

Chlorinated polyether coatings have excellent chemical resistance and are widely used to coat equipment for the chemical industry such as valves, pipe and pipe fittings, pump housings and impellers, electroplating jigs and fixtures, cams, and bushings. However, chlorinated polyether coatings should not be used in contact with some chlorinated organic solvents, or with fuming sulfuric and nitric acids.

Fluidized-Bed Heating

Heating carried out in a medium of solid particles suspended in a flow of gas.

Fluidized-Bed Reduction

The finely divided solid is a powdered ore or reducible oxide, and the moving gas is reducing; the operation is carried out at elevated temperature in a furnace.

Fluorescence

(1) Emission of electromagnetic radiation that is caused by the flow of some form of energy into the emitting body and which ceases abruptly when the excitation ceases. (2) Emission of electromagnetic radiation that is caused by the flow of some form of energy into the emitting body and whose decay, when the excitation ceases, is temperature-independent. (3) A type of photoluminescence in which the time interval between the absorption and re-emission of light is very short. (4) If emission continues after radiation has ceased the phenomenon is termed phosphorescence. Contrast with *phosphorescence*.

Fluorescent Magnetic-Particle Inspection

Inspection with either dry magnetic particles or those in a liquid suspension, the particles being coated with a fluorescent substance to increase the visibility of the indications.

Fluorescent Penetrant Inspection

Inspection using a fluorescent liquid that will penetrate any surface opening; after the surface has been wiped clean, the location of any surface flaws may be detected by the fluorescence, under ultraviolet light, of back-seepage of the fluid.

Fluorimetry

See *fluorometric analysis*.

Fluorinated Ethylene Propylene (FEP)

A member of the fluorocarbon family of plastics that is a copolymer of tetrafluoroethylene and hexafluoroethylene, possessing most of the properties of poly-tetrafluoroethylene, and having a melt viscosity low enough to permit conventional thermoplastic processing. Available in pellet form for molding and extrusion, and as dispersions for spray or dip coating processes.

Fluorine

An elementary material, symbol F, which at ordinary temperatures is an irritating pale-yellow gas, F_2 . Fluorine gas is obtained by the reduction and electrolysis of fluorspar and cryolite. It is used in the manufacture of fluorine compounds. It combines violently with water to form hydrofluoric acid, and it also reacts strongly with silicon and most metals. Liquid fluorine is used as an oxidizer for liquid rocket fuels. In combustion, a pound of fluorine produces a pound of hydrogen fluoride which is highly corrosive. Fluorine is one of the most useful of the halogens.

The gas *sulfur hexafluoride*, SF_6 , resembles nitrogen in its inactivity. It is odorless, colorless, nonflammable, nontoxic, and five times as heavy as air. It is used as a refrigerant, as a dielectric medium in high-voltage equipment, as an insecticide propellant, and as a gaseous diluent. *Aluminum fluoride*, AlF_3 , is a white crystalline solid used in ceramic glazes and for fluxing nonferrous metals.

Chlorine- and bromine-free *perfluorocarbon fluids*, of 3 M, are intended for spot-free drying of metal parts, replacing those on-depleting chlorofluorocarbons.

Fluorocarbons

The family of plastics including polytetrafluoroethylene, polychlorotrifluoroethylene, polyvinylidene, and fluorinated ethylene propylene. They are characterized by good thermal and chemical resistance, nonadhesiveness, low dissipation factor, and low dielectric constant. They are available in a variety of forms, such as molding materials, extrusion materials, dispersions, film, or tape, depending on the particular fluorocarbon.

These are any of the organic compounds in which all of the hydrogen atoms attached to a carbon atom have been replaced by fluorine. Fluorocarbons are usually gases or liquids at room temperature, depending on the number of carbon atoms in the molecule. A major use of gaseous fluorocarbons is in radiation-induced etching processes for the microelectronics industry; the most common one is tetrafluoromethane. Liquid fluorocarbons possess a unique combination of properties that has led to their use as inert fluids for cooling of electronic devices and soldering. Solubility of gases in fluorocarbons has also been used in biological cultures requiring O_2 , and as liquid barrier filters for purifying air.

Fluorocarbons may be made part fluorocarbon and part fluorocarbon, or may contain chlorine. The fluorocarbons used as plastic resins may contain as much as 65% fluorine and also chlorine, but

are very stable. Liquid fluorocarbons are used as heat-transfer agents, hydraulic fluids, and fire extinguishers. Benzene-base fluorocarbons are used for solvents, dielectric fluids, lubricants, and for making dyes, germicides, and drugs. Synthetic lubricants of the fluorine type consist of solid particles of a fluorine polymer in a high-molecular weight fluorocarbon liquid. Chlorine reacts with fluorocarbons to form chlorofluorocarbons, commonly referred to as CFCs. CFC 11 is used as a foam-blowing agent, and CFC 12 is employed as a refrigerant. CFC 113 is a degreasant in semiconductor manufacturing. Because they are strong depletants of stratospheric ozone, the use of CFCs as aerosol propellants has been banned in the United States since 1978, and is being phased out in Europe. Alternatives to CFCs are being sought for other applications by partially substituting the chlorine with other elements. CFC 22, which has 95% less ozone-depleting capacity than CFC 12, is a potential candidate to replace CFC 12.

Fluorometric Analysis

A method of chemical analysis that measures the fluorescence intensity of the analyte or a reaction product of the analyte and a chemical reagent.

Fluoroplastics

Plastics based on polymers with monomers containing one or more atoms of fluorine, or copolymers of such monomers with other monomers, with the fluorine-containing monomer (s) being in greatest amount by mass.

Also termed fluoropolymers, fluorocarbon resins, and fluorine plastics, fluoroplastics are a group of high-performance, high-price engineering plastics. They are composed basically of linear polymers in which some or all of the hydrogen atoms are replaced with fluorine, and are characterized by relatively high crystallinity and molecular weight. All fluoroplastics are natural white and have a waxy feel. They range from semirigid to flexible. As a class, they rank among the best of the plastics in chemical resistance and elevated temperature performance. Their maximum service temperature ranges up to about 260°C. They also have excellent frictional properties and cannot be wet by many liquids. Their dielectric strength is high and is relatively insensitive to temperature and power frequency. Mechanical properties, including tensile creep and fatigue strength, are only fair, although impact strength is relatively high.

PTFE, FEP, and PFA

There are three major classes of fluoroplastics. In order of decreasing fluorine replacement of hydrogen, they are fluorocarbons, chlorotrifluoroethylene, and fluorohydrocarbons. There are two fluorocarbon types: tetrafluoroethylene (PTFE or TFE) and fluorinated ethylene propylene (FEP). PTFE is the most widely used fluoroplastic. It has the highest useful surface temperature, 260°C, and chemical resistance.

Their high melt viscosity prevents PTFE resins from being processed by conventional extrusion and molding techniques. Instead, molding resins are processed by press-and-sinter methods similar to those of powder metallurgy or by lubricated extrusion and sintering. All other fluoroplastics are melt processable by techniques commonly used with other thermoplastics.

PTFE resins are opaque, crystalline, and malleable. When heated above 341°C, however, they are transparent, amorphous, relatively intractable, and they fracture if severely deformed. They return to their original state when cooled.

F

The chief advantage of FEP is its low melt viscosity, which permits it to be conventionally molded. FEP resins offer nearly all of the desirable properties of PTFE, except thermal stability. Maximum recommended surface temperature for these resins is lower by about 37.8°C. Perfluoro-alkoxy (PFA) fluorocarbon resins are easier to process than FEP and have higher mechanical properties at elevated temperatures. Service temperature capabilities are the same as those of PTFE.

PTFE resins are supplied as granular molding powders for compression molding or ram extrusion, as powders for lubricated extrusion, and as aqueous dispersions for dip coating and impregnating. FEP and PFA resins are supplied in pellet form for melt extrusion and molding. FEP resin is also available as an aqueous dispersion.

Teflon is a tetrafluoroethylene of specific gravity up to 2.3. The tensile strength is up to 23.5 MPa, elongation 250%–350%, dielectric strength 39.4×10^6 V/m, and melting point 312°C. It is water resistant and highly chemical resistant. Teflon S is a liquid resin of 22% solids, sprayed by conventional methods and curable at low temperatures. It gives a hard, abrasion-resistant coating for such uses as conveyors and chutes. Its temperature service range is up to 204°C. Teflon fiber is the plastic in extruded monofilament, down to 0.03 cm in diameter, oriented to give high strength. It is used for heat- and chemical-resistant filters. Teflon tubing is also made in fine sizes down to 0.25 cm in diameter with wall thickness of 0.03 cm. Teflon 41-X is a colloidal water dispersion of negatively charged particles of Teflon, used for coating metal parts by electrodeposition. Teflon FEP is fluorinated ethylenepropylene in thin-film, down to 0.001 cm thick, for capacitors and coil insulation. The 0.003 cm film has a dielectric strength of 126×10^6 V/m, tensile strength of 20 MPa, and elongation of 250%.

Properties

Outstanding characteristics of the fluoroplastics are chemical inertness, high- and low-temperature stability, excellent electrical properties, and low friction. However, the resins are fairly soft and resistance to wear and creep is low. These characteristics are improved by compounding the resins with inorganic fibers or particulate materials. For example, the poor wear resistance of PTFE as a bearing material is overcome by adding glass fiber, carbon, bronze, or metallic oxide. Wear resistance is improved by as much as 1000 times, and the friction coefficient increases only slightly. As a result, the wear resistance of filled PTFE is superior, in its operating range, to that of any other plastic bearing material and is equaled only by some forms of carbon.

The static coefficient of friction for PTFE resins decreases with increasing load. Thus, PTFE bearing surfaces do not seize, even under extremely high loads. Sliding speed has a marked effect on friction characteristics of unreinforced PTFE resins; temperature has very little effect.

PTFE resins have an unusual thermal expansion characteristic. A transition at 18°C produces a volume increase of over 1%. Thus, a machined part, produced within tolerances at a temperature on either side of this transition zone, will change dimensionally if heated or cooled through the zone.

Electrical properties of PTFE, FEP, and PFA are excellent, and they remain stable over a wide range of frequency and environmental conditions. Dielectric constant, for example, is 2.1 from 60 to 10^9 Hz. Heat-aging tests at 300°C for 6 months show no change in this value. Dissipation factor of PTFE remains below 0.0003 up to 10^8 Hz. The factor for FEP and PFA resins is below 0.001 over the same range. Dielectric strength and surface arc resistance of fluorocarbon resins are high and do not vary with temperature or thermal aging.

CTFE or CFE

Chlorotrifluoroethylene (CTFE or CFE) is stronger and stiffer than the fluorocarbons and has better creep resistance. Like FEP and unlike PTFE, it can be molded by conventional methods.

Sensitivity to processing conditions is greater in CTFE resins than in most polymers. Molding and extruding operations require accurate temperature control, flow channel streamlining, and high pressure because of the high melt viscosity of these materials. With too little heat, the plastic is unworkable; too much heat degrades the polymer. Degradation begins at about 274°C. Because of the lower temperatures involved in compression molding, this process produces CTFE parts with the best properties.

Thin parts such as films and coil forms must be made from partially degraded resin. The degree of degradation is directly related to the reduction in viscosity necessary to process a part. Although normal, partial degradation does not greatly affect properties, seriously degraded CTFE becomes highly crystalline, and physical properties are reduced. Extended usage above 121°C also increases crystallinity.

CTFE plastic is often compounded with various fillers. When plasticized with low-molecular-weight CTFE oils, it becomes a soft, extensible, easily shaped material. Filled with glass fiber, CTFE is harder, more brittle, and has better high-temperature properties.

Properties

CTFE plastics are characterized by chemical inertness, thermal stability, and good electrical properties, and are usable from 400 to –400°C. Nothing adheres to these materials, and they absorb practically no moisture. CTFE components do not carbonize or support combustion. Up to thicknesses of about 3.2 mm, CTFE plastics can be made optically clear. Ultraviolet absorption is very low, which contributes to its good weatherability.

Compared with PTFE, FEP, and PFA fluorocarbon resins, CTFE materials are harder, more resistant to creep, and less permeable; they have lower melting points, higher coefficients of friction, and are less resistant to swelling by solvents than the other fluorocarbons.

Tensile strength of CTFE moldings is moderate, compressive strength is high and the material has good resistance to abrasion and cold flow. CTFE plastic has the lowest permeability to moisture vapor of any plastic. It is also impermeable to many liquids and gases, particularly in thin sections.

PVF₂ and PVF

The fluorohydrocarbons are of two kinds: polyvinylidene fluoride (PVF₂) and polyvinyl fluoride (PVF). Although similar to the other fluoroplastics, they have somewhat lower heat resistance and considerably higher tensile and compressive strength.

Except for PTFE, the fluoroplastics can be formed by molding, extruding, and other conventional methods. However, processing must be carefully controlled. Because PTFE cannot exist in a true molten state, it cannot be conventionally molded. The common method of fabrication is by compacting the resin in powder form and then sintering.

PVF₂, the toughest of the fluoroplastic resins, is available as pellets for extrusion and molding and as powders and dispersions for corrosion-resistant coatings. This high-molecular-weight homopolymer has excellent resistance to stress fatigue, abrasion, and to cold flow. Although insulating properties and chemical inertness of PVDF are not as good as those of the fully fluorinated polymers, PTFE and FEP, the balance of properties available in PVDF qualifies this resin for many engineering applications. It can be used over

the temperature range from -73°C to 149°C and has excellent resistance to abrasion.

PVDF can be used with halogens, acids, bases, and strong oxidizing agents, but it is not recommended for use in contact with ketones, esters, amines, and some organic acids.

Although electrical properties of PVDF are not as good as those of other fluoroplastics, it is widely used to insulate wire and cable in computer and other electrical and electronic equipment. Heat-shrinkable tubing of PVDF is used as a protective cover on resistors and diodes, as an encapsulant over soldered joints.

Valves, piping, and other solid and lined components are typical applications of PVDF in chemical-processing equipment. It is the only fluoroplastic available in rigid pipe form. Woven cloth made from PVDF monofilament is used for chemical filtration applications.

A significant application area for PVDF materials is as a protective coating for metal panels used in outdoor service. Blended with pigments, the resin is applied, usually by coil-coating equipment, to aluminum or galvanized steel. The coil is subsequently formed into panels for industrial and commercial buildings.

A recently developed capability of PVDF film is based on the unique piezoelectric characteristics of the film in its so-called beta phase. Beta-phase PVDF is produced from ultrapure film by stretching it as it emerges from the extruder. Both surfaces are then metallized, and the material is subjected to a high voltage to polarize the atomic structure.

When compressed or stretched, polarized PVDF generates a voltage from one metallized surface to the other, proportional to the induced strain. Infrared light on one of the surfaces has the same effect. Conversely, a voltage applied between metallized surfaces expands or contracts the material, depending on the polarity of the voltage.

PFA, ECTFE, and ETFE

The following three fluoroplastics are melt processable. Perfluoroalkoxy (PFA) can be injection-molded, extruded, and rotationally molded. Compared to FEP, PFA has slightly greater mechanical properties at temperatures over 150°C and can be used up to 260°C .

Ethylene-chlorotrifluoroethylene (ECTFE) copolymer resins also are melt processable with a melting point of 240°C . Their mechanical properties—strength, wear resistance, and creep resistance, in particular—are much greater than those of PTFE, FEP, and PFA, but their upper temperature limit is about 165°C . ECTFE also has excellent property retention at cryogenic temperatures.

Ethylene-tetrafluoroethylene (ETFE) copolymer resin is another melt-processable fluoroplastic with a melting point of 270°C . It is an impact-resistant, tough material that can be used at temperatures ranging from cryogenic up to about 179°C .

One of the advantages of the copolymers of ethylene and TFE—called modified ETFE—and of ethylene and CTFE—called ECTFE—compared with PTFE and CTFE is their ease of processing. Unlike their predecessors, they can be processed by conventional thermoplastic techniques. Various grades can be made into film or sheet, into a monofilament, or used as a powder coating; all grades can be heat-sealed or welded.

Although these resins have lower heat resistance than PTFE or CTFE, they offer a combination of properties and processability that is unattainable in the predecessor resins. Maximum service temperature for no-load applications is in the range of 149°C – 199°C for ETFE and ECTFE, compared with 199°C for CTFE and 288°C for PTFE. Glass reinforcement increases these values by 10°C .

Both tensile strength and toughness of these resins are higher than those of the other fluoropolymers; they are rated “no break”

in notched Izod tests. The modulus of ECTFE is higher than that of ETFE up to about 100°C ; above 150°C , ETFE has a higher modulus.

As with other fluoroplastics, these resins are compatible with most chemicals, even at high temperatures. ETFE is not attacked by most solvents to temperatures as high as 199°C . ECTFE is similar to 121°C , but is attacked by chlorinated solvents at higher temperatures. ETFE has better chemical stress-crack resistance.

Applications for these resins include wire and cable insulation, chemical-resistant linings and molded parts, laboratory ware, and molded electrostructural parts.

Fluoroscopy

An inspection procedure in which the radiographic image of the subject is viewed on a fluorescent screen, normally limited to low-density materials or thin sections of metals because of the low light output of the fluorescent screen at safe levels of radiation.

Fluorspar

Also called fluorite, fluorspar is a crystalline or massive granular mineral of the composition CaF_2 , used as a flux in the making of steel, for making hydrofluoric acid, in opalescent glass, in ceramic enamels, for snaking artificial cryolite, as a binder for vitreous abrasive wheels, and in the production of white cement. It is a better flux for steel than limestone, making a fluid slag, and freeing the iron of sulfur and phosphorus. About 2.5 kg of fluorspar is used per ton of basic open-hearth steel.

Acid spar is a grade used in making hydrofluoric acid. It is also used for making refrigerants, plastics, and chemicals, and for aluminum reduction. Optical fluorspar is the highest grade but is not common. Fluoride crystals for optical lenses are grown artificially from acid-grade fluorspar. Pure calcium fluoride, Ca_2F_6 , is a colorless crystalline powder used for etching glass, in enamels, and for reducing friction in machine bearings. It is also used for ceramic parts resistant to hydrofluoric acid and most other acids. Calcium fluorite has silicon in the molecule and is a crystalline powder used for enamels. The clear rhombic fluoride crystals used for transforming electric energy into light are lead fluoride, PbF_2 .

Flush Weld

A weld with surfaces following the profile of the parent materials. The profile may be formed directly by welding or, more often, by subsequent grinding, machining, etc.

Flushing (of Weld)

Machining or grinding the surface of a weld to bring it flush with the parent surfaces. The term underflushing is ambiguous, being used to indicate either insufficient or excessive flushing.

Flute

(1) As applied to drills, reamers, and taps, the channels or grooves formed in the body of the tool to provide cutting edges and to permit passage of cutting fluid and chips. (2) As applied to milling cutters and hobs, the chip space between the back of one tooth and the face of the following tooth.

Fluted Bearing

A sleeve bearing with oil grooves generally in an axial direction.

F

Fluted Core

An integrally woven reinforcement material consisting of ribs between two skins in a unitized *sandwich construction*.

Flutes

Elongation grooves or voids that connect widely spaced cleavage planes.

Fluting

(1) Forming longitudinal recesses in a cylindrical part, or radial recesses in a conical part. (2) A series of sharp parallel kinks or creases occurring in the arc when sheet metal is roll formed into a cylindrical shape. (3) Grinding the grooves of a twist drill or tap. (4) In bearings, a form of pitting in which the pits occur in a regular pattern so as to form grooves. Ridges may occur with or without burnt craters. The general cause involves vibration together with excessive wear or excessive load. (5) Electric discharge pitting in a rolling-contact bearing subject to vibration. (6) A fracture process whereby *flutes* are produced.

Flux

(1) In metal refining, a material added to a melt to remove undesirable substances, like sand, ash, or dirt. Fluxing of the melt facilitates the agglomeration and separation of such undesirable constituents from the melt. It is also used as a protective covering for certain molten metal baths. Lime or limestone is generally used to remove sand, as in iron smelting; sand, to remove iron oxide in copper refining. (2) In brazing, cutting, soldering, or welding, material used to prevent the formation of, or to dissolve and facilitate removal of, oxides and other undesirable substances. (3) A material or compound applied or introduced in various processes, usually involving melting or heating, to react with undesirable materials such as impurities in the bulk material or contaminants on the surface. The material formed by the combination of the flux and the contaminants forms a slag which is readily separated from the product. (4) The density of magnetic lines of force. (5) A measure of nuclear intensity, the number of particles per unit volume times the mean particle velocity. (6) Rate of heat input. Units include J/s and Btu/h.

Flux is a substance added to a refractory material to aid in its fusion. A secondary action of a flux, which may also be a primary reason for its use, is as a reducing agent to deoxidize impurities.

Any material that lowers the melting temperature of another material or mixture of materials is a flux. Fluxing substances may occur as natural impurities in a raw material. Thus, the alkali content of a clay will flux the clay. In other cases, fluxes are separate raw materials. Example: use of feldspar to flux a mixture of clays and flint.

An auxiliary flux is a third component that may make the primary flux more effective. Thus, addition of 2% dolomite, talc, or fluorspar to a whiteware mixture that contains 25% feldspar will produce a substantial decrease in vitrification temperature. The auxiliary constituent may be incapable of producing the same result (or too expensive to use) as the sole flux.

Compounds of alkali metals (sodium, potassium, and lithium) are popular fluxes for clay bodies. Compounds of alkaline earth metals (calcium, magnesium, and, to a lesser extent, barium and strontium) are common auxiliary fluxes. However, they also may

be primary fluxes for such products as low-loss dielectrics. Lead and boron compounds are important fluxes for glasses, glazes, and enamels. And pre-melted glasses or frits may be used to flux clay or other bodies.

The term *flux* also may be used to specify a low-melting glass used in decorating glass products or an overglaze for clayware. Pigments are mixed with the powdered glass flux and then applied to the object to produce a vitrifiable coating at temperatures <650°C.

Fluxing alloys for brasses and bronzes are phosphor tin, phosphor copper, or silicon copper. They deoxidize the metals at the same time that alloying elements are added. For tinning steel, palm oil is used as a flux. For ordinary soldering, zinc chloride is a common flux. Tallow, rosin, or olive oil may also be used for soldering. Acetamide is used for soldering painted metals. For silver braze filler metals, borax is a common flux. For soldering stainless steel, borax is mixed with boric acid, or pastes are made with zinc chloride and borax. Borax may also be used as a welding flux. *White flux* is a mixture of sodium nitrate and nitrite and is a strong oxidizer used for welding. Other fluxes used in brazing contain potassium chloride, lithium fluoride, boric acid, borates, and fluoroborates.

Welding fluxes for high-temperature welding are usually coated on the rod and contain a deoxidizer and a slag former. *Lithium fluoride*, LiF, is a powerful flux with the fluxing action of both lithium and fluorine, and it gives a low-melting-point liquid slag. Deoxidizers may be ferromanganese or silicon-manganese. *Slag formers* are titanium dioxide, magnesium carbonate, feldspar, asbestos, or silica. Soluble silicate is a binder, while cellulose may be used for shielding the arc.

Flux Cored Arc Welding (FCAW)

An arc welding process that joins metal by heating them with an arc between a continuous tubular filler-metal electrode and the work. Shielding is provided by a flux contained within the consumable tubular electrode. Additional shielding may or may not be obtained from an externally supplied gas or gas mixture. See also *electrogas welding*.

Flux Cored Electrode

A composite filler metal electrode consisting of a metal tube or other hollow configuration containing ingredients to provide such functions as shielding atmosphere, deoxidation, arc stabilization, and slag formation. Alloying materials may be included in the core. External shielding may or may not be used.

Flux Cover

In metal bath dip brazing and dip soldering, a cover of flux over the molten filler metal bath.

Flux Density

In magnetism, the number of *flux lines* per unit area passing through a cross-section at right angles. It is given by $B = \mu H$, where μ and H are permeability and magnetic-field intensity, respectively.

Flux Lines

Imaginary lines used as a means of explaining the behavior of magnetic and other fields. Their concept is based on the pattern of lines

produced when magnetic particles are sprinkled over a permanent magnet. Sometimes called magnetic lines of force.

Flux Oxygen Cutting

Oxygen cutting with the aid of a flux.

Flux Solder Connection

A solder joint characterized by entrapped flux that often causes high electrical resistance in electronic component.

Fly Ash

A finely divided siliceous material formed during the combustion of coal, coke, or other solid fuels.

Fly Cutting

Cutting with a single-tooth milling cutter.

Flying Shear

A machine for cutting continuous rolled products to length that does not require a halt in rolling, but rather moves along the runout table at the same speed as the product while performing the cutting, and then returns to the starting point in time to cut the next piece.

Foam Inhibitor

A surface-active chemical compound used in minute quantities to prevent or reduce *foaming*. Silicone fluids are frequently used as foam inhibitors.

Foam Materials

These are materials with a sponge-like, cellular structure. They include the well-known sponge rubber, plastic foams, glass foams, refractory foams, and a few metal foams. Ordinary chemically blown sponge rubber is made up of interconnecting cells in a labyrinth-like formation. When made by heating latex, it may show spherical cells with the porous walls perforated by the evaporation of moisture. It is also called foam rubber. Special processes are used to produce cell-tight and gas-tight cellular rubber, which is nonabsorbent.

Cellular rubber comes in sheets of any thickness for gaskets, seals, weather stripping, vibration insulation, and refrigerator insulation. Most of the so-called sponge rubbers are not made of natural rubber but are produced from synthetic rubbers or plastics, and may be called by a type classification, such as urethane foam.

Others include phenolic foam, which is made by incorporating sodium bicarbonate and an acid catalyst into liquid phenol resin. The reaction liberates CO_2 gas, expanding the plastic.

Cellular cellulose acetate is expanded with air-filled cells for use as insulation and as a buoyancy material for floats. It is tough and resilient. *Strux* is cellulose acetate foam, made by extruding the plastic mixed with barium sulfate in an alcohol-acetone solvent. When the pressure is removed, it expands into a light, cellular structure. Polystyrene foam is widely used for packaging and for building insulation. It is available as prefoamed board or sheet, or as beads that expand when heated.

Styrofoam is polystyrene expanded into a multicellular mass 42 times the original size. It has only one-sixth the weight of cork, but will withstand hot water or temperatures above 77°C , as it is thermoplastic. It is used for cold-storage insulation, and is resistant to mold. Polyethylene foam and polypropylene foam are also available. Compared with expanded polystyrene, expanded polyolefins have greater toughness and can be molded more easily. Current uses include automotive bumper cores, sun visor cores, and electronic packaging.

Other foams include foamed vinyl plastisols and expanded polyvinyl chloride. Polyester foam is odorless, flame-resistant, and resistant to oils and solvents. It has only half the weight of foamed rubber with greater strength and high resistance to oxidation. It is used for upholstery and insulation.

Silicone foam, used for insulation, is silicone rubber foamed into a uniform unicellular structure. Vinyl foams are widely used and they are made from various types of vinyl resins with the general physical properties of the resin used. Epoxy foams come as a powder consisting of an epoxy resin mixed with diaminodiphenyl sulfone. Glass foam is used as thermal insulation for buildings, industrial equipment, and piping. Ceramic foams of alumina, silica, and mullite are used principally for high-temperature insulation. Aluminum foam is a metal foam that has found appreciable industrial use as a core material in sandwich composites. Foamed zinc is a lightweight structural metal with equal strength in all directions, made by foaming with an inert gas into a closed cell structure. It is used particularly for shock and vibration insulation. Foaming agents for metals are essentially the same as those used for plastics. They are chemical additives that release a gas to expand the material by forming closed bubbles. Or they may be used to cause froth as in detergents or fire-fighting foams.

Foam Polymers

Most polymers, thermoplastics, or thermosets can be expanded into a foam by the addition of a foaming or blowing agent. They can be foamed to desired density, ranging from near the weight of solid resin, at over $64.08 \times 10^{-2} \text{ g/cm}^3$, to extremely light, at $1.602 \times 10^{-2} \text{ g/cm}^3$. The foamed product will maintain the general characteristics of the base resin as its mechanical properties decrease along with its density.

Thermoplastic Foams

Thermoplastic foams can be extruded by heating the resin and blowing agent to a threshold temperature, causing the blowing agent to react and expand into a gas. The gas combines with the resin, forming a frothy mass that is extruded through a shaping die. The resulting buns, logs, or sheets can then be cut into shapes for inclusion in composite panels and other applications.

Bead foaming is accomplished by heating resin beads that include the blowing agent in the formulation. A mold cavity is partially filled with beads and heated to the temperature at which the blowing agent gives off gas. This causes the softened beads to expand, filling the mold and welding them together. The process commonly used to make polystyrene foam creates slab stock or shapes molded to specific dimensions. Foam stock forms can be mechanically knife-cut or band-sawed into sheets, blocks, or other desired shapes.

Thermoset Foams

Some type of liquid foaming is necessary to manufacture thermoset foams, used primarily for the rigid structural foam-type applications mentioned earlier. The liquid formulation for these foams

F

contains not only the base resin and blowing agent, but also the catalyst required for curing in thermoset chemistry. Liquid foaming techniques, which include spraying, can be employed for open- or closed-mold processes and often include a reinforcement or filler material.

Polyurethane

Polyurethane, long considered a workhorse of low-cost foams, can be formed by first reacting two liquid components together. Water is the principle blowing agent (fluorocarbon is also used). This reaction produces CO_2 , which is trapped in closed cells, giving good thermal insulation to the foam. Depending on the reaction and the chemicals or additives used, the foams can either be soft and flexible or tough, hard, and rigid.

Cell Structure and Density

Polymer foams have either open- or closed-cell structures, depending primarily on the type of resin and foaming process employed. Closed-cell foams, which dominate the marine industry, are impermeable, preventing water ingress. Depending on the resin chemistry used, closed-cell foams may also be impervious to corrosive liquid chemicals and solvents, making them useful as an insulating material for industrial tanks.

Most low-density ($1.05\text{--}3.20 \times 10^{-2} \text{ g/cm}^3$) rigid urethane foams have a closed-cell content of 90% or greater in slab form. Under controlled conditions, the closed-cell content can be increased to 99%.

Medium- to high-density polyurethane foams ($4.81\text{--}64.08 \times 10^{-2} \text{ g/cm}^3$) can be formulated with various characteristics and diverse high-performance capabilities that range from insulating and isolating toxic industrial wastes and radioactive nuclear materials to sandwich panels requiring higher modulus and high-temperature resistance for use in aircraft.

Higher-density, heavier foams, sometimes formulated with phenolic resins, are more dimensionally stable at elevated temperatures. Low-density foams may swell when exposed to elevated temperatures because of gas expansion and increased pressure from inner cell air and moisture. If this happens, foam cells will then erupt and collapse, since internal pressure is necessary to maintain cell structure. Contraction can continue until the foam becomes so dense that it resembles a solid more than a foamed plastic.

Foam Additives and Reinforcements

A variety of additives can be included in foam formulations that greatly impact the density, cost, manufacturability, and performance characteristics of the finished product. Randomly distributed short-fiber reinforcements can be blown into foam during spray-up, which become an integral part of the cell walls. Fiber in mat, fabric, or long-fiber form can also be introduced into the mold. Mechanical properties of the finished product will increase dramatically with the introduction of fiber reinforcements. From low-cost mineral fillers, to microspheres and oriented fiber webs, new reinforced foam products are being developed that offer elegant, low-cost solutions to esoteric application requirements.

Structural Foam

Structural foam, SRIM-type constructions, are similar in configuration to laminated sandwich panels. They have full-density outer skins and lightweight cellular cores, and the relative benefits

inherent in this type of configuration, such as high stiffness-to-weight and strength-to-weight ratios, are similar to sandwich panels as well. These rigid foam products, usually made with polyurethane-based chemistry, are often reinforced, enhancing their mechanical properties.

Structural foams are made using both high- and low-pressure processes. When products are made using high pressure, the mold is solidly filled under pressure with unfoamed resin; then it is expanded (or a core removed) and the foaming agent is activated or injected to form the core layer. High-pressure processes are able to provide dense, smooth skins and achieve high levels of surface detail. Tooling for these processes is usually relatively expensive.

In low-pressure methods, the mold is partially filled with molten resin that expands to fill the mold and forms a skin upon contact with the walls. In the past, there has been some concern about surface quality with self-skinning open-molded structural foams but recent advances in resin chemistry and molding techniques are producing class A finishes for demanding automotive applications under low pressures.

Applications

Sandwich Panel Construction

One of the oldest and best-understood uses for foam core materials is in the construction of structural sandwich panels. The typical sandwich panel consists of strong outer laminate skins made with oriented glass, carbon, or aramid fiber and a lightweight inner core.

Tailoring foam core selection to the specific application is especially important. When failure of a sandwich panel occurs, it is usually in the core, because plastic foams have low shear rigidity compared to the skins. The core material must be strong enough to stabilize the sandwich structure, providing a shear load path between the laminate skins to prevent buckling.

An inexpensive foam product, a lightweight, non-chlorofluorocarbon-blown polyisocyanurate, *ELFOAM* is a product for insulation applications, where nonwoven fiberglass incorporates webs within the foam to carry the structural load in the design for structural sandwich panel construction. The foam is co-cured by resin infusion or pressurized processes and the dry fiber provides channels through which resin is drawn into the core. This offers high strength-to-weight and stiffness-to-weight ratios, creating tough, thick, lightweight structures ideal for industrial or construction applications.

Boatbuilding

Commercial boatbuilding has used composite materials over the years. Tough, durable thermoplastic PVC foam formulations are the most commonly used marine panel applications. In fact, the educated consumer has grown to appreciate and demand the lightweight, self-insulating, low-condensation improvements provided by two fiberglass skins over a foam core.

Another resin option designed for boat hull applications that must withstand repeated exposure to dynamic loads is linear structural foam. The new chemistry addresses the discrepancy between anti-modulus core with no flexure and a flexural core with low modulus. *Core-Cell* is a linear formulation that offers the stiffness of cross-linked PVCs, while maintaining its plastic range for high impact and damage tolerance. *Core-Cell* has heat distortion temperature comparable to cross-linked PVC foams, making it suitable for deck and superstructure laminates.

There is also a spray-applied foam for marine applications that is based on polyester/polyurethane hybrid chemistry. For use in

open-mold processes only, the unsaturated polyester provides stiffness and hardness, and the polyurethane enables a fast cure and internal toughness.

The spray-applied foam provides high flexural modulus and flexural strength. It can be sprayed at a 0.38–12.7 mm thickness to provide structural strength at less weight than fiber-reinforced plastics/polyester. Ultracore foams are bondable with epoxy, vinyl ester, and polyurethane resins.

High-Performance Foams

High-performance foam core materials are typically striving for exceptionally high-temperature resistances or strength-to-weight ratios, or for other esoteric properties. These are generally derived from state-of-the-art resin chemistry or additives. Cores made from resins with exotic chemistries like polymethacrylimide (PMI) or bismaleimide (BMI) lend themselves to use in aerospace applications that demand dimensional stability at temperatures up to 149°C. For example, *Rohacell PMI* rigid foams have been selected for the interstage and payload fairings of the Delta II–IV rockets. These components are co-cured in thermoformed-to-shape sandwich cores. Rohacell XT is the newest, closed-cell isotropic foam with an extended temperature grade available that is suitable for use with BMI prepreg skins, co-curing at temperatures up to 190°C with a 232°C postcure.

Syntactic foams are an entirely different concept in foam technology. Cell structure is created by incorporating hollow microspheres into a compound (usually a liquid resin), eliminating the need for a blowing agent. The microspheres can be made from a variety of materials such as glass, diatomaceous earth, or plastic, with foam density controlled by how much resin is used to hold the microspheres together. Deriving properties primarily from the microsphere material, syntactic foams are highly customizable for esoteric applications.

Foam-Filled Honeycomb

Honeycomb cores, filled with foam and sandwiched between laminates, offer both high static-load and dynamic-load properties, as well as high fatigue endurance, strength and stiffness, and resistance to localized compression of random loads. Combining honeycomb and foam technologies in a single product raises the mechanical properties significantly. Additionally, the foam technology provides flexibility, memory, good elongation properties, and shear strength of 1.7 MPa and above.

Foaming

In tribology, the production and coalescence of gas bubbles on a liquid lubricant surface.

Foaming Agent

Chemicals added to plastics and rubbers that generate inert gases, such as nitrogen, upon heating, causing the resin to form a cellular structure.

Focal Length

In an optical microscope, the distance from the second principal point to the point on the axis at which parallel rays entering the lens will converge or focus.

Focal Point

See preferred term *focal spot*.

Focal Spot

(1) That area on the target of an x-ray tube that is bombarded by electrons. (2) The area of the x-ray tube from which the x-rays originate. The effective focal-spot size is the apparent size of this area when viewed from the detector. (3) In electron beam and laser beam welding, a spot at which an energy beam has the most concentrated energy level and the smallest cross-sectional area.

Focus

In microscopy, a point at which rays originating from a point in the object converge or from which they diverge or appear to diverge under the influence of a lens or distracting system.

Focusing Device, Electrons

A device that effectively increases the angular aperture of the electron beam illuminating the object, rendering the focusing more critical.

Focusing, X-Rays

The operation of producing a convergent beam in which all rays meet in a point or line.

Fog Quenching

Quenching in fine mist or spray. It gives a cooling rate intermediate between air cooling and quenching into oil.

Foil

Foil is very thin sheet metal used chiefly for wrapping, laminating, packaging, insulation, and electrical applications. Tinfoil is higher in cost than some other foils, but is valued for wrapping food products because it is not poisonous; it has now been replaced by other foils such as aluminum.

Lead foil, used for wrapping tobacco and other nonedible products, is rolled to the same thickness as tinfoil, but because of its higher specific gravity gives less coverage. Stainless steel foil is produced in thicknesses from 0.005 to 0.038 cm for laminating and for pressure-sensing bellows and diaphragms.

Aluminum foil has high luster, but is not as silvery as tinfoil. The tinfoil usually has a bright side and a matte side because two sheets are rolled at one time. Aluminum foil also comes with a satin finish, or in colors or embossed designs. For electrical use the foil is 99.999% pure aluminum, but foil for rigid containers is usually aluminum alloy 3003, with 1%–1.5% manganese, and most other foil is of aluminum alloy 1145, with 99.45% aluminum. The tear resistance of thin aluminum foil is low, and it is often laminated with paper for food packaging. Trifoil is aluminum foil coated on one side with Teflon and on the other with an adhesive. It is used as coatings for tables and conveyors or liners in chemical and food plants. Since polished aluminum reflects 96% of radiant heat waves, this foil is applied to building boards or used in crumpled form in walls for insulation.

F

Aluminum yarn, for weaving ribbons, draperies, and dress goods, is made from aluminum foil, 0.003–0.008 cm thick, by gang-slitting to widths from 0.0317 to 0.3175 cm and winding the thread on spools. Gold foil is called gold leaf and is not normally classed as foil. It is used for architectural coverings and for hot-embossed printing on leather. It is made by hammering in books, and can be made as thin as 0.0000083 cm, a gram of gold covering 3.4 m². Usually, goldleaf contains 2% silver, and copper for hardening.

Metal film, or metal foil, for overlays for plastics and for special surfacing on metals or composites, comes in thicknesses from flexible foils as thin as 0.005 cm to more rigid sheets for blanking and forming casings for intricately shaped parts. There are many types of hot-stamping foils, including metallic pigment foils, printed foils, and vacuum metallized foils. Composite metal films come in almost any metal or alloy such as film of tungsten carbide in a matrix of nickel alloy for wear-resistant overlays.

Foil Bearing

A bearing in which the housing is replaced by a flexible foil held under tension against a partition of the journal periphery, lubricant being retained between the journal and the foil.

Foil Decorating

Molding paper, textile, or plastic foils printed with compatible inks directly into a plastic part so that the foil is visible below the surface of the part as integral decoration.

Fold

(1) A defect in metal, usually on or near the surface, caused by continued fabrication of overlapping surfaces. (2) A forging defect caused by folding metal back onto its own surface during its flow in the die cavity. See also *lap*.

Folded Chain

The confirmation of a flexible polymer when present in a crystal. The molecule exits and reenters the same crystal, frequently generating folds.

Folic Acid

Sodium folate, a yellow to yellow-orange liquid used in medicine for folic acid deficiency. It is known as *folic acid sodium salt*, *folacin*, and, in its biologically active form, *folate*.

It is a B vitamin known to prevent spina bifida and anencephaly, devastating birth defects and may be effective in preventing cardiovascular diseases and common cancers. Foods rich in the nutrient include chicken liver in various grains, cereals, beans, vegetables, nuts, and fruit juices.

Follow Board

In foundry practice, a board contoured to a pattern to facilitate the making of a sand mold.

Follow Die

A *progressive die* consisting of two or more parts in a single holder; used with a separate lower die to perform more than one operation (such as piercing and blanking) on a part in two or more stations.

Follower Plate

A plate fitted to the top surface of a grease dispenser.

Fools Gold

Iron pyrites, FeS₂, which can resemble gold.

Foot Press

A small press with a low capacity actuated by foot pressure on a treadle.

Force Fit

Any of various interference fits between parts assembled under various amounts of force. See *interference fit*.

Force Plug

The male half of the mold for making plastics that enters the cavity, exerting pressure on the resin and causing it to flow. Also called punch. Sometimes called a core, plunger, or ram.

Forced-Air Quench

A quench utilizing blasts of compressed air against relatively small parts such as a gear.

Force-Feed Lubrication

See *pressure lubrication*.

Forehand Welding

(1) The technique of manual gas welding in which the flame both points and moves forward to the unwelded joint. Any filler rod points back toward the completed weld. Also termed forward welding and leftward welding although the latter may give rise to some confusion in the case of left-handed operators. (2) Welding in which the palm of the principal hand (torch or electrode hand) of the welder faces the direction of travel. It has special significance in oxyfuel gas welding in that the flame is directed at the head of the weld bead, which provides *preheating*. Contrast with *backhand welding*. See also *push angle*, *travel angle*, and *work angle*.

Foreign Atom

Atoms of an element other than that forming the bulk of the crystal structure.

Foreign Structure

Any metallic structure that is not intended as part of a *cathodic protection* system of interest.

Forensic Science

The application of scientific techniques to assist in matters of civil and criminal law.

Forge Delay Time

In spot, seam, or projection welding, the time between the start of the welding, current or weld interval and the application of forging pressure.

Forge Roll Scleroscope Hardness Number (HFRSc or HFRSd)

A number related to the height of rebound a diamond-tipped hammer dropped on a forged steel roll. It is measured on a scale determined by dividing into 100 units the average rebound of a hammer from a forged steel roll of accepted maximum hardness. See also *Scleroscope hardness number* and *Scleroscope hardness test*.

Forge Structure

The microstructure through a suitable section of a forging that reveals direction of working.

Forge Welding

Solid-state welding in which metals are heated in a forge (in air) and then welded together by applying pressure or blows sufficient to cause permanent deformation at the interface. The process is most commonly applied to the butt welding of steel.

Forge Welding Die

A device used in *forge welding* primarily to form the work while hot and apply the necessary pressure.

Forgeability

Term used to describe the relative ability of material to deform without fracture. Also describes the resistance to flow from deformation. See also *formability*.

Forging

The process of working metal to a desired shape by impact or pressure in hammers, forging machines (upsetters), presses, rolls, and related forming equipment. Forging hammers, counter-blow equipment, and high-energy-rate forging machines apply impact to the workpiece, while most other types of forging equipment apply squeeze pressure in shaping the stock. Some metals can be forged at room temperature, but most are made more plastic for forging by heating. Specific forging processes include *closed-die forging*, *high-energy-rate forging*, *hot upset forging*, *isothermal forging*, *open-die forging*, *powder forging*, *precision forging*, *radial forging*, *ring rolling*, *roll forging*, *rotary forging*, and *rotary swaging*.

Forging Billet

A wrought metal slug used as *forging stock*.

Forging Dies

Forms for making forgings; they generally consist of a top and bottom die. The simplest will form a completed forging in a single

impression; the most complex, consisting of several die inserts, may have a number of impressions for the progressive working of complicated shapes. Forging dies are usually in pairs, with part of the impression in one of the blocks and the rest of the impression in the other block.

Forging Envelope

See *finish allowance*.

Forging Ingot

A cast metal slug used as *forging stock*.

Forging Machine (Upsetter or Header)

A type of forging equipment, related to the mechanical press, in which the principal forming energy is applied horizontally to the workpiece, which is gripped and held by prior action of the dies. See also *heading*, *hot upset forging*, and *upsetting*.

Forging Plane

In forging, the plane that includes the principal die face and that is perpendicular to the direction of ram travel. When parting surfaces of the dies are flat, the forging plane coincides with the parting line. Contrast with *parting plane*.

Forging Quality

Term used to describe stock of sufficient quality to make it suitable for commercially satisfactory forgings.

Forging Range

Temperature range in which a metal can be forged successfully. See the term *forgeability*.

Forging Rolls

Power-driven rolls used in preforming bar or billet stock that have shaped contours and notches for introduction of the work. See also *roll forging*.

Forging Stock

A wrought rod, bar, or other section suitable for subsequent change in cross-section by forging.

Forgings

Forging is a process of plastic deformation, usually at elevated temperatures, of ingot, bar, or billet, mill product, or metal powder to produce a desired shape and mechanical properties. Forging develops a metallurgical sound, uniform, and stable material that will have optimum properties in the operating component after being completely processed and assembled.

During the forging process, metal is distributed within the required shape as it is needed according to function and stress requirements for purposes of improved design, material utilization, producibility, and cost. Forged integral components permit

F

reduction in the number of mechanical and welded joints and elimination of welds in critical areas, with resultant reduction in stress concentrations, increased reliability and weight savings.

Forging processes are usually classified either by the type of equipment used or by the geometry of the end product. The simplest forging operation is upsetting, which is carried out by compressing the metal between two flat parallel platens. From this simple operation, the process can be developed into more complicated geometries with the use of dies. A number of variables are involved in forging; among major ones are properties of the workpiece and die materials, temperature, friction, speed of deformation, die geometry, and dimensions of the workpiece. One basic principle in forging is the fact that the material flows in the direction of least resistance.

Forgeability

In practice, forgeability is related to the strength, ductility, and friction of the material. Because of the great number of factors involved, no standard forgeability test has been devised. For steels, which constitute the majority of forgings, torsion tests at elevated temperatures are the most predictable; the greater the number of twists of a round rod before failure, the greater is its ability to be forged. A number of other tests, such as simple upsetting, tension, bending, and impact tests, have also been used.

In terms of factors such as ductility, strength, temperature, friction, and quality of forging, various engineering materials can be listed as follows in order of decreasing forgeability; aluminum alloys, magnesium alloys, copper alloys, carbon and low-alloy steels, stainless steels, titanium alloys, iron-base superalloys, cobalt-base superalloys, columbium alloys, tantalum alloys, molybdenum alloys, nickel-base alloys, tungsten alloys, and beryllium.

Types of Forging Methods

All methods of forging are basically related to hammering or pressing; the main difference between the two is the speed of pressure application. At times, the two methods may be interchangeable, depending on the availability of equipment and forging characteristics of the alloy. Certain metals and alloys resist rapid deformation and require the normally slower pressing operation.

Hammers are energized by gravity, air, or steam, and repeated blows of a vertically guided ram on metal (usually heated) resting on the anvil cause the metal to change shape. The steam hammer is generally used in the modern forge shop because of its flexibility of operation.

Pressing causes metal to move as the result of a slowly applied force. Presses operate by hydraulic, air, or steam action or by mechanical means such as crank or screw. Hydraulic presses have slower action than hammers, and their pressure application may be more closely controlled, allowing the maintenance of sustained pressures. Mechanical action presses, particularly of the crank type, may closely approach the speed of hammer blows and cannot maintain sustained pressures.

Although presses are usually assumed to operate in a vertical plane, upsetters, which fall into the category of mechanical presses, operate in a horizontal plane with side or gripper dies moving in coordination and at 90° to the basic press movement. Ring rolling machines come in various designs, but fundamentally operate as presses, with moving rolls forcing the ring to the desired shape and size. Extrusion presses may operate either vertically or horizontally.

Swaging or, as it is also called, rotary swaging consists of two or four dies which are activated radially by blocks in contact with a series of rollers. The rotation of the block die assembly causes the curved ends of the blocks (either circular or modified sine curve) to be in contact with the rollers; relative motion between the blocks and the roller housing then gives a reciprocating motion to the dies. The hammering action on the outer surface of the stock reduces its diameter; the stock is generally prevented from rotating.

Die Types

In forging, force is transmitted to the workpiece through dies generally made of chromium–molybdenum–vanadium steels, sometimes modified by addition of nickel or tungsten. In open dies, the primary force (compression) is applied locally, and different parts of the forging are progressively worked. In closed dies, the primary force is applied on the entire surface and the metal is forced into a cavity for forging to shape.

Open die (or hand) forgings are produced either in a hammer or a press, using a minimum of tooling. This method offers low tool cost and fast initial delivery, but relatively poor utilization of material and slow production rates. Closed die forgings involve higher tool cost for small quantities of finished parts, but offer relatively good utilization of material, generally better properties, close tolerances, good production rates, and good reproducibility.

Flat die forgings are produced on the anvil and offer simple configurations. Blocker-type forgings have fairly generous design tolerances and are usually made in one set of closed dies. Normal (or commercial) dies impart a more exact configuration to the workpiece that may be machined to required tolerances. No-draft close-tolerance dies impart a finished shape and size to the forging, which requires little or no machining. Generally, precision is inversely proportional to size, melting point of the metal, forging temperature, and the reactive tendencies of the metal surface with the atmosphere and lubricants at the forging temperature. Precision is directly proportional to the number of dies used.

With most configurations, therefore, economics dictate that it is cheaper to machine a commercial forging than to continue to approach the finish tolerances with die forgings alone.

Advantages of Forgings

Orientation of crystal structure of the base metal and the flow pattern distribution of secondary phases (nonmetallics and alloy segregation) aligned in the direction of working is called grain flow. Metals in the solid state are a crystalline aggregate and are, therefore, anisotropic to a degree in properties such as strength, ductility, and impact and fatigue resistance. This anisotropy or directionality can be employed to the desired extent by orienting the metal during forging (through die design) in the direction requiring maximum strength.

It is possible to develop the maximum strength potential of a particular alloy in the forging process. Only quality-controlled rolled bar or cast ingot stock is used. Quality is determined by chemical analysis, microstructure, macrostructure, ultrasonics, and mechanical testing. Further improvement comes during the forging process, because work on the material itself achieves recrystallization and grain refinement to produce material for optimum heat-treatment response.

Forgings are better than cast material for many applications because of their greater strength and ductility in a particular alloy as well as greater soundness, uniformity in chemistry, and finer

grain size. There is no drastic change of state or volume in forging as there is in castings during solidification.

Forgings are highly reproducible because of this, and because of the use of carefully controlled material, controlled working temperatures, and controlled metal flow in specially designed permanent die cavities. Forged components are also stronger than welded fabrications because weld efficiencies rarely equal 100%. Ordinary sintered products do not develop the full strength potential of an alloy because of porosity in the sintered part. As a result, a larger section is required for equivalent strength, but even here, ductility will be appreciably lower than in a part forged from material of the same chemistry.

Forgings, designed to approach the desired finished part configuration, make better utilization of material than parts machined from plate or bar stock. The closeness of this approach will be determined by the amount of money desired to be spent on forge tools rather than machining capacity. Also, bar or plate stock has only one direction of grain flow. As a result, changes in section size cut across flow lines and render the material more notch, fatigue, and stress-corrosion sensitive.

Other Comparisons

Forging vs. Stamping

Stampings are suitable at most levels of production, but are most economical where annual production is high. Press productivity and die costs logically depend on the number of dies and presses required. The list price of sheet stock is competitive with forging stock, but stamping is not usually as material efficient. Energy consumption, however, is low since the stock is not heated.

Six factors give forging advantages over sheet metal stamping.

1. The engineered scrap rate for some types of stampings that are alternatives to forging maybe as high as 50%.
2. Most stampings are made in stages requiring separate dies. Processing costs climb as the number of dies increases.
3. Many applications require several stampings to be separately formed and joined in an assembly. Production costs climb with the amount of tooling, fixturing, and joining required. In some cases forgings have been chosen over one-piece stampings to achieve weight advantages or to gain secondary benefits from shapes that cannot be stamped.
4. Stampings are usually made from stock of uniform thickness. The stock thickness of a stamping is driven by the mechanical requirements of one critical feature. Alternatives, such as added reinforcements or tailored blanks, require separate parts to be processed or joined. Forging allows designers to tailor feature thickness to functional requirements, reducing overall component weight.
